## DECLARACIÓN

“Yo, Ana Belén Lozada Miniguano, declaro bajo juramento que el trabajo aquí descrito es de mi autoría; que no ha sido previamente presentado para ningún grado o calificación profesional; y, que he consultado las referencias bibliográficas que se incluyen en este documento.

Sin perjuicio de los derechos reconocidos en el primer párrafo del artículo 114 del Código Orgánico de la Economía de los Conocimientos, Creatividad e Innovación –COESC-, cedo los derechos patrimoniales de este trabajo, a la Escuela Politécnica Nacional.”

---

Ing. Ana Belén Lozada Miniguano  
C.I. 0503610602

## CERTIFICACIÓN

Certifico que el presente trabajo fue desarrollado por Ana Belén Lozada Miniguano, bajo mi supervisión.

---

Ing. Lucía Eliana Manangón Perugachi MSc.  
**DIRECTORA DE TESIS**

## **AUSPICIO**

La presente investigación contó con el auspicio financiero del proyecto PII-DEMEX-2020-03, que se ejecutó en el Departamento de Metalurgia Extractiva de la Facultad de Ingeniería Química y Agroindustria.

## **AGRADECIMIENTOS**

A Dios, por ser quien me fortalece y levanta en momentos de debilidad, por su constante muestra de amor y protección, por forjar mi camino y mi carácter, y por enseñarme que, a pesar de las dificultades, todas las cosas obran para bien.

A mi amada madre Gema, por su esfuerzo inmedible y su amor invaluable, por ser ese descanso para mi alma, por cada palabra de calma, de ánimo, y de fortaleza, y por ser mi ejemplo todos los días. Gracias por ser y estar siempre.

A mi querida hermana Jaqueline, por su cariño, apoyo y consejos, por su compañía siempre, y por inculcarme orden, disciplina y constancia.

A la memoria de mi padre Víctor, por el cuidado y protección en sus días, y por enseñarme que todas las cosas importantes se logran con firmeza, decisión y perseverancia. Te extraño siempre.

A memoria de mi abuelito Ricardo, por ser el ser más dulce, amoroso, y bondadoso que he conocido. Dios fue tan bueno al permitirme crecer a tu lado.

A mi Abuelita María, por las risas y el buen ánimo que imparte.

A mi tíos y primos, de forma especial a Hipatia, Holger, Roberto, Diana, Sayana, Doménica, y Juliet, gracias por su apoyo y cariño incondicional a lo largo de mi vida.

A mi directora de tesis, Ing. Eliana Manangón, por la dirección y el apoyo total en la realización de este trabajo. Un agradecimiento especial por la confianza, amistad, y estima, gracias por compartir sus conocimientos y permitirme aprender de Ud. Es una excelente persona y profesional.

Al personal docente y administrativo del Departamento de Metalurgia Extractiva de la Escuela Politécnica Nacional por su colaboración y disposición. Al Ing. Ernesto de la Torre, Ing. Diana Endara, Ing. Alicia Guevara, Ing. Eddy Pazmiño, Ing. Evelyn Criollo, Ing. Carlos Aragón, Ing. Kleber Collantes, Sra. Verito Díaz, y Wilmer Betun, gracias por contribuir cada uno en diferentes aspectos.

A la segunda cohorte de esta maestría, Patricia Jaramillo, Edmundo Cruz, y Luis Huilca, por el conocimiento y la experiencia compartidos.

A una persona muy importante, Solange Esquivel, por ser esa amiga incondicional, por estar siempre dispuesta a escuchar, por tu bondad y buen corazón. Gracias por qué de ti puedo recibir un consejo que siempre me hará bien.

A mi amiga Nathaly Rodríguez, por el cariño, apoyo, y buenos momentos que hemos podido compartir. Mi admiración a tu tesón y buen ánimo en todo lo que haces.

A personas que, con sus palabras de ánimo y sus deseos de superación, han hecho más llevadera esta etapa de estudio, Angie Huanga, por su carisma, cariño y por todos los momentos divertidos que hemos compartido. A Eduardo Rueda y Luis Zambrano, por su amistad y apoyo. A familia de la IBDSA. Gracias siempre.

## DEDICATORIA

Dedico este trabajo con mucho amor y satisfacción a mi amada familia: a mi madre Gema Miniguano y a mi hermana Jaqueline Lozada, por ser mi apoyo y fortaleza en cada momento de mi vida. A mi padre Víctor Lozada (+) por sembrar en mí un compromiso de trabajo constante, dedicación, y superación. A mis abuelitos Ricardo (+) y María por ser ese reflejo de amor, ternura y cuidado.

En gratitud a su esfuerzo y amor, procuraré dar siempre lo mejor de mí.

*“Cuanto más grande es la dificultad, más gloria hay en superarla.*

*Epicuro”.*

9 **Resumen:** Las silicalitas de titanio son catalizadores que se han utilizado exitosamente en reacciones  
10 de oxidación selectiva por lo que se han desarrollado algunas alternativas para potenciar su  
11 actividad. Una de ellas es la modificación de la hidrofobicidad de la superficie de estos catalizadores.  
12 El carácter hidrofóbico de los catalizadores juega un papel importante en los procesos de  
13 adsorción/desorción de reactivos y productos y, en consecuencia, en el rendimiento catalítico. La  
14 hidrofobización de las silicalitas de titanio se ha estudiado en varias investigaciones, pero aún no se  
15 ha revisado el efecto sobre su actividad catalítica. Además, las metodologías para medir la  
16 hidrofobicidad difieren en cada investigación dificultando la comparación de esta propiedad. Por  
17 esta razón, en este trabajo se compararon silicalitas de titanio amorfas y cristalinas modificadas  
18 hidrofóticamente. Se compararon y discutieron las metodologías usadas para la hidrofobización,  
19 las técnicas de caracterización de la hidrofobicidad y el efecto sobre su actividad catalítica. Se ha  
20 obtenido una mejora significativa en la medición de la hidrofobicidad como resultado de la  
21 combinación de dos o más técnicas analíticas. Sin embargo, no se puede atribuir la mejora en la  
22 actividad catalítica totalmente a la modificación de la hidrofobicidad debido a la complejidad de los  
23 sistemas de reacción y las interacciones entre la superficie del catalizador y el medio de reacción.  
24 Por lo cual, se requieren estudios más extensos para comprender mejor el efecto de la  
25 hidrofobización de la superficie de las silicalitas de titanio y otros catalizadores sólidos porosos.

26 **Abstract:** Titanosilicates are catalysts which have been successfully used in selective oxidation  
27 reactions whereby, some alternatives have been developed to enhance their activity. One of these is  
28 the modification of the hydrophobicity of the catalyst surface. The hydrophobicity of these materials  
29 plays an important role on the adsorption/desorption processes and consequently, on the catalytic  
30 performance. Several researchers have studied the hydrophobization of titanosilicates, but the effect  
31 on their catalytic activity has not been reviewed yet. In addition, the methodologies to measure the  
32 hydrophobicity differ in each work making difficult the comparison of this property. For this reason,  
33 in this work crystalline and amorphous titanosilicates that have been modified hydrophobically  
34 were addressed. A comparison and discussion of the methodologies for hydrophobic modification,  
35 the analytical techniques for characterization of hydrophobicity, and the effect of hydrophobization  
36 on their catalytic activity were performed. A significant improvement of hydrophobicity  
37 characterization has been reached as a result of the combination of two or more analytical  
38 techniques. However, the improved catalytic activity cannot be totally attributed to the hydrophobic  
39 modification due to the complexity of the reaction systems, interactions between catalyst surface  
40 and liquid medium. Thus, more extensive studies including kinetic, thermodynamic, spectroscopy,  
41 and computational analysis are required to gain more understanding of the effect of  
42 hydrophobizing the surface of titanosilicates and other porous solid catalysts.

44 density

## 45 Introduction

46 Titanosilicates are important materials with fast development since the synthesis of the first TS-  
47 1 [1–5]. They are used in selective oxidation of organic compounds displaying high catalytic activity.  
48 [1,2,6–11]. The growing application of these heterogeneous catalysts for both petrochemical and fine  
49 chemical industry has resulted in a substantial production of titanosilicates with improved catalytic  
50 performance which could replace the traditional ones [12]. In fact, more than 400 articles per year  
51 have been published in the last 5 years, according to a search in the Scopus database.

52 The active sites of titanosilicates are Ti atoms in tetrahedral coordination (also called framework-  
53 Ti) which are inserted in the silica framework. According to previous studies, a limit for isomorphous  
54 substitution of Ti atoms into the TS-1 framework was established at a maximum atomic ratio of 2.5%  
55 ( $\text{Ti} / (\text{Si} + \text{Ti})$ ) [13] to prevent the formation of octahedral Ti species (extraframework Ti), which is not  
56 active in selective oxidation reactions. For instance, when the Ti content in TS-1 was higher than 3%,  
57 octahedral Ti, which is the same Ti species present in the crystalline phase of  $\text{TiO}_2$  (anatase), was  
58 detected by DRUV-Vis [14] and XPS [15]. In selective oxidation reactions, Ti active sites interact with  
59 the oxidant ( $\text{H}_2\text{O}_2$  or organic peroxides) to produce Ti-peroxo intermediate species (Ti-OOH or Ti-  
60 OOR) which are the active catalytic oxidation centers [14,16,17]. It is known that tetrahedral Ti in  
61 titanosilicates displays Lewis acidity which activates the oxidant, forming the activated complex that  
62 reacts with substrates such as olefins in epoxidation reactions [18–22].

63 Some alternatives have been used to improve the catalytic performance of titanosilicates, such  
64 as improving the textural properties [2,12], controlling the nature of the active sites [1,23], and  
65 modifying the hydrophobic/philic surface character. In the last years, the adjustment of  
66 hydrophobicity/philicity of materials such as metal-organic-frameworks (MOFs) [24–26],  
67 aluminosilicates [27], and titanosilicates [28] has received more attention due to its great influence  
68 over their catalytic properties.

69 In the field of titanosilicates, the effect of hydrophobization has been particularly studied in the  
70 epoxidation of olefins in liquid phase. For instance, some authors believed that the hydrophobicity  
71 of titanosilicates affected the competitive adsorption between non-polar substrates (olefin) and polar  
72 products (epoxide) [29,30]. Consequently, several researchers focused on studying the effect of  
73 hydrophobizing titanosilicates to improve the olefin adsorption. Later, studies showed that  
74 epoxidation follows an Eley-Rideal mechanism, in which, only the oxidant is adsorbed on the  
75 catalysts surface, but a hydrophobic surface allows the rapid removal of epoxide preventing the  
76 oxidation to diol [31]. In addition, a hydrophobic surface reduces water adsorption that would cause  
77 the epoxide ring opening and deactivation of the titanium active sites [32]. Water is added to the  
78 reaction together with the oxidant. For example, the commercially available  $\text{H}_2\text{O}_2$  is normally a  
79 30%(w/w) solution in water. Thus, the modification of the hydrophobicity of the surface of  
80 titanosilicates could regulate the interaction between the catalyst with both the reactants and  
81 products and prevent side reactions, resulting in high conversion and/or selectivity [33].

82 Several crystalline and amorphous titanosilicates have been hydrophobized by different  
83 methodologies. TS-1, which is already a hydrophobic titanosilicate was further hydrophobized by  
84 controlling the silanol surface density to improve its catalytic activity. The use of  $(\text{NH}_4)_2\text{CO}_3$  as  
85 crystallizing agent allows to regulate the silanol density of TS-1, and it also reduces the presence of  
86 extraframework Ti. The defects of the material decreased by increasing the degree of crystallization.  
87 The improved hydrophobic character and Ti dispersion of TS-1 yielded a significant increment of the  
88 activity of the catalyst [34]. Also, hydrophobic TS-1 functionalized by post-grafting achieved higher  
89 epoxide selectivity than non-modified one [35].

90 The small pores of TS-1 allow the catalytic oxidation of relatively small molecules efficiently, but  
91 its use in oxidation of greater substrates is restricted due to diffusion limitations. Therefore, large-  
92 pore titanium zeolites were synthesized to tackle this limitation. Ti-Beta zeolite has better textural  
93 properties than TS-1 zeolite, but it is more hydrophilic [36]. Therefore, Ti-Beta was hydrophobized  
94 by the synthesis in fluoride medium instead of the classical  $\text{OH}^-$  medium. Hydrophobization of Ti-  
95 Beta helped to decrease the silanol surface density [37–39]. For many years, it was believed that

96 hydrophobic Ti-Beta performed better in catalytic epoxidation than the hydrophilic analogous, but a  
97 recent study published by Bregante et al. [39] demonstrated that hydrophilic Ti-Beta exhibits  
98 turnover rates 100 times larger than the hydrophobic one. This discrepancy highlights the necessity  
99 to clarify the real effect of the hydrophobization of Ti-Beta. Other large-pore titanosilicates such as  
100 Ti-MCM-41 [40–44], Ti-MCM-48 [42], and Ti-SBA-15 [33], and amorphous Ti-SiO<sub>2</sub> [11,45–49] were  
101 functionalized by one-pot and post-grafting procedures and showed greater catalytic performance in  
102 the epoxidation of olefins.

103 It is notable that hydrophobic properties of catalysts surfaces display an important role into the  
104 adsorption/desorption processes and consequently, in the catalytic performance of titanosilicates. In  
105 fact, several researchers have studied the hydrophobization of these materials and the modification  
106 resulted in positive, negative, or non-significant effects on their catalytic activity. Even though the  
107 modification of hydrophobicity has been addressed in previous investigations, the variety of types  
108 of titanosilicates and the analytical techniques used to measure this property has not allow to reach  
109 a consensus in the catalytic effects of hydrophobization. From the best of our knowledge, there is not  
110 yet a review article analyzing this effect. For this reason, a comparison and discussion about the  
111 effects of hydrophobization of titanosilicates will be here addressed, considering the type of  
112 titanosilicate, the hydrophobization strategy, the surface characterization, and the catalytic system.

### 113 Section 1: Overview of the topic

#### 114 1.1 Types of titanosilicates and description of their characteristics focusing on their active site and textural 115 properties.

116 Titanosilicates, both crystalline and amorphous are important materials with fast development  
117 from this inception [1–5]. The importance of these materials lies in their remarkable catalytic activity  
118 in selective oxidation reactions. Ordered titanosilicates have been employed as catalysts in selective  
119 oxidation of organic compounds (i.e., alkanes, alkenes, alcohols, aromatics) in liquid-phase using  
120 hydrogen peroxide and organic peroxides as oxidants [1,2,6]. Amorphous titanosilicates are  
121 conventional catalysts for olefins epoxidation [7–11]. Titanosilicates have been constantly developed  
122 since of the first Ti-zeolite TS-1 was synthesized in 1983. As shown in Figure 1, the number of  
123 publications per year related to titanosilicates has increased through the years.

124 124

125 **Figure 1** Number of publications per year related to titanosilicates. Source: Scopus, June 2021.

126 In this work, titanosilicates are considered as materials that contain titanium atoms inserted in  
127 a silica matrix. We have classified them into two groups, the first group being formed by the  
128 titanosilicates based on zeolite frameworks (Ti-zeolite) that are crystalline materials and the second  
129 group including titanosilicates without zeolite framework (Ti-SiO<sub>2</sub>) with amorphous structure.

### 130 1.1.1 Active sites of titanosilicates

131 Various types of titanosilicates with zeolitic as well as amorphous structure have been  
132 synthesized. All titanosilicates contain Ti<sup>4+</sup> transition metal. Zeolites have shown a significant impact  
133 on catalysis technology. A variety of zeolites containing atoms other than Al<sup>3+</sup> (heteroatoms i.e., Ti<sup>4+</sup>,  
134 Sn<sup>4+</sup>, Ga<sup>4+</sup>) have been created and employed in acid-catalyzed reactions with higher performance than  
135 the traditional SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> catalysts [50].

136 Ti atoms were introduced into the silica matrix by isomorphous substitution of Si<sup>4+</sup> by Ti<sup>4+</sup> [51].  
137 The substitution of Si<sup>4+</sup> by heteroatoms in the crystalline lattice has been extensively studied since  
138 this replacement can produce important effects on the physical, chemical, and catalytic properties  
139 [52,53]. An important parameter to be considered is that Ti can be inserted into the zeolite structure  
140 in tetrahedral and/or octahedral coordination. In fact, minerals with Na, Ti and Si (zorite and  
141 vinogradovite) contain Ti atoms in octahedral coordination. In addition, the ionic ratio (cation  
142 radius/anion radius) of Ti-O bond corresponding to 0.515 exceeds the range of 0.225 to 0.414 to  
143 produce tetrahedral coordination. Thus, the isomorphous substitution of Si<sup>4+</sup> by Ti<sup>4+</sup> seemed  
144 improbable [54].

145 The substitution of Si<sup>4+</sup> by Ti<sup>4+</sup> in the TS-1 titanosilicate was verified by modification of the unit-  
146 cell parameters as a function of the substitution degree and the difference between Si-O and Ti-O  
147 bond distance. No substantial changes were detected in XRD spectra of TS-1 compared with silicalite-  
148 1 and the minor changes were attributed to the formation of titanium dioxide which corresponds to  
149 octahedral coordination (extraframework titanium, EFW-Ti (Figure 1b)). This means that the  
150 isomorphous substitution cannot be perfect. Subsequent studies reached great development about  
151 the synthesis and reproducibility of TS-1 in industrial laboratories. According to TS-1  
152 characterization, it was possible to determine that Si<sup>4+</sup> was mainly substituted by Ti<sup>4+</sup> in tetrahedral  
153 coordination (framework titanium, FW-Ti (Figure 1a)) [50]. In the case of TS-1 the substitution limit  
154 based on the lattice constants is around 2.5% (Ti/(Ti+Si)). Above this value, EFW-Ti appears [55].  
155 There is not a theoretical value for all types of zeolites since it depends on the structure type and the  
156 presence of internal defects (Si-OH groups), whichever the synthesis methodology [23].

157 157

158 **Figure 2** Titanium species in titanosilicates: a) Framework titanium (FW-Ti) and b) Extraframework  
159 titanium (EFW-Ti).

160 Different analytical techniques were developed for better characterization of Ti sites in  
161 titanosilicates such as Fourier transform infrared spectroscopy (FTIR), Raman vibrational  
162 spectroscopies, Electron Paramagnetic Resonance (EPR), X-Ray Absorption Fine Structure (EXAFS),  
163 X-Ray Absorption Near Edge Structure (XANES), and Diffuse Reflectance DRUV-Vis. Specifically,  
164 tetrahedral titanium can be detected by Infrared/Raman band at  $960\text{ cm}^{-1}$  and UV peak at  $210\text{ nm}$   
165 (absorption in  $330\text{ nm}$  exhibits the presence of octahedral Ti). The presence of tetrahedral Ti has even  
166 been associated to a change of color to yellow upon the addition of  $\text{H}_2\text{O}_2$  to a TS-1. An interesting  
167 compilation of these analytic procedures was presented by Vayssillov in 2008 [1].

168 The presence of EFW-Ti affects the catalytic activity of titanosilicates in selective oxidation  
169 reactions since EFW-Ti is not active for these reactions, increases the  $\text{H}_2\text{O}_2$  decomposition, and blocks  
170 the access of reactants to internal Ti active sites [1]. Tetrahedral Ti active sites react with the oxidant  
171 to produce surface titanium peroxo complexes which oxidize organic substrates including olefins  
172 [56].

### 173 1.1.2 Acidity

174 Acidity in zeolites was originated from the substitution of  $\text{Si}^{4+}$  by different heteroatoms. In  
175 principle, zeolites are composed by  $\text{SiO}_4$  units, in which the positive charge of  $\text{Si}^{4+}$  is balanced with  
176 the negative charge of oxygens, thus  $\text{SiO}_4$  is electrically neutral. In the case of aluminosilicates, a  
177 disequilibrium of charges is produced due to the substitution of  $\text{Si}^{4+}$  by  $\text{Al}^{3+}$ , and organic or inorganic  
178 cations or protons (i.e.  $\text{H}^+$ ) are introduced to achieve electrical neutrality [50,57].

179 It was found that the introduction of  $\text{Al}^{3+}$  in the zeolitic framework can produce both Brønsted  
180 acid sites (BAS) and Lewis acid sites (LAS). BAS are produced by the bridging between the  
181 tetrahedrally coordinated  $\text{Al}^{3+}$  with neighboring hydroxyls (Si-OH-Al on the surface of the zeolite  
182 framework), and LAS are assigned to extraframework Al [58]. Bridging hydroxyl groups Si-OH-Al  
183 as well as silanol groups (Si-OH) on the surface of the zeolite form BAS, and both catalyze oxidation  
184 reactions. The formation of Si-OH-Al is related to the Si/Al ratio, thus a decrement in the Si/Al ratio  
185 (higher Al content) results in the increment of Si-OH-Al [59–62].

186 BAS are also related to the hydrophobicity/hydrophilicity of zeolites. Previous studies  
187 demonstrated that Si-O-Si bonds are hydrophobic [63], and hydroxyl groups (Si-OH and Si-OH-Al)  
188 are hydrophilic [64]. Free-defect siliceous surfaces formed by Si-O-Si bridges present resistance to  
189 adsorbing water [63], while hydroxyl groups adsorb water molecules and water clusters [64]. The  
190 hydrophilic character increases while the surface density of silanol groups increases [65]. In fact,  
191 according to Cundy et al., the hydrophobicity index (HI) decreased with the increase of BAS [66]. The  
192 presence of hydroxyl groups on the catalysts surface is determined from the absorption in the  $3200$ -  
193  $3800\text{ cm}^{-1}$  region of the infrared spectra on dehydrated samples [23]. Brønsted acidity is evaluated by  
194 measuring the wavenumber shift after adsorption of probe molecules (CO, tert-butyl nitrile,  
195 acetonitrile and pyridine) [67–69].

196 Titanol groups (Ti-OH) could also contribute to the Brønsted acidity of titanosilicates. Some  
197 studies detected both silanol and titanol groups in TS-1 [70] and other titanosilicates such as Ti-SBA-  
198 15 [33] and Ti-TUD-1 [71]. In contrast, other studies found that the insertion of  $\text{Ti}^{4+}$  atoms in the  
199 framework did not generate Brønsted acid detectable sites. For example, the characteristic band at  
200  $3676\text{ cm}^{-1}$  was not detected in dehydrated TS-1. In fact, this band appeared after contact with  $\text{H}_2\text{O}_2$ .  
201 In the structure of TS-1, neighboring Si vacancy defects produce internal hydrogen-bonded silanols  
202 (Si-OH) which can act as weak Brønsted acid sites [72].

203 On the other hand,  $\text{Ti}^{4+}$  atoms in titanosilicates act as Lewis acid sites (LAS). It has been  
204 extensively studied that LAS catalyze efficiently oxidation reactions [23]. LAS were detected by  
205 infrared spectroscopy using acetonitrile as probe molecule in adsorption experiments [73]. Other Ti  
206 active species with different Lewis acidic strengths can also affect the oxidation mechanism (i.e.,  
207 distorted tetrahedral species, tripodal  $\text{Ti}(\text{OSi}_3\text{OH})$  and octahedral Ti), but there is a consensus that  
208 the species with the highest Lewis acidity are the most capable of oxidizing organic substrates such  
209 as olefins [23,31].

## 210 1.1.3 Titanosilicates based on zeolite frameworks (Ti-zeolite)

211 Ti-zeolites have a crystalline structure composed of SiO<sub>4</sub> tetrahedral units in which one or more  
 212 Si atoms can be replaced by Ti atoms without introducing negative charges [74]. Ti-zeolites have been  
 213 used as catalysts of selective oxidation reactions (e.g., epoxidation of olefins, hydroxylation of phenol,  
 214 ammoximation of ketone, oxidative desulfurization and oxidation of pyridine derivatives) [75].

215 The differences in shape, size and channel topology of zeolites enable their use in a wide range  
 216 of industrial applications. In addition, Ti-zeolites are important not only for the technical  
 217 performance but also, they are environmentally friendly since the optimization of these catalysts has  
 218 turn certain processes more efficient and less waste is generated, following the principles of green  
 219 chemistry [2].

220 There is extensive information available about Ti-zeolites; for instance, Ratnasamy and co-  
 221 workers in 2004 published the stat-of-the-art about the active sites and intermediate Ti species in  
 222 crystalline titanosilicates [23]. Later in 2014, Moliner and Corma reviewed the advances in the  
 223 preparation of ordered titanosilicates focusing on the texture [74]. An important contribution about  
 224 the latest progress in the synthesis of titanosilicates was stated by Xu and Wu in 2017; in which  
 225 topology, morphology and chemical environment were analyzed [12]. Recently in 2018, Přeč  
 226 described the catalytic performance of titanosilicates in selective oxidation reactions [2].

227 Přeč presented a precise classification of Ti-zeolites according to their textural properties,  
 228 shape, pore size, Ti active sites content and Ti active sites location. In Přeč's publication, Ti-zeolites  
 229 were divided in 4 groups: i) conventional Ti-zeolites (Table 1) with same order of magnitude of the 3  
 230 crystal dimensions without cavities and other defects, ii) hierarchical Ti-zeolites that exhibit typical  
 231 micropore structure (zeolitic structure) and more or less ordered system of mesopores (20-430 Å in  
 232 diameter), iii) lamellar Ti-zeolites containing mesoporous between lamellae, and iv) mesoporous  
 233 titanosilicates with amorphous structure, but ordered system of mesopores (20 Å) [2].

234 **Table 1** Pore size of conventional Ti-zeolites. Adapted from Přeč [2].

Group	Sub-group	Ring pores	Diameter (Å)
Conventional Ti-zeolites	Medium-pore	10	4.5-5.5
	Large-pore	12	5.5-7.0
	Extra-large-pore	14	>7.0

235

236 Since the synthesis of TS-1, more than 30 Ti-zeolites (Table 2) have been developed. However,  
 237 only few of them, including Ti-Beta, Ti-MWW, Ti-MOR have been used on industrial scale [12,75].  
 238 TS-1 has been efficiently used as catalyst of oxidation of small molecules using aqueous H<sub>2</sub>O<sub>2</sub> as  
 239 oxidant. However, TS-1 and other medium-pore Ti-zeolites such as Ti-YNU-2 [76] presented  
 240 limitations in the diffusion of reactants and products due to its intrinsic microporosity. Large  
 241 substrates such as linear olefins or phenol cannot access to the internal active sites causing the  
 242 reaction to occur only on the outer surface [77,78]. In order to solve this limitation, new Ti-zeolites  
 243 have been synthesized including large-pore Ti-zeolites as: Ti-MCM-41 [79], Ti-MCM-48 [80], Ti-Beta  
 244 [81] and Ti-MOR [82], and extra-large Ti-UTL [83].

245 Another alternative to improve the porosity and exposure of the active sites is the introduction  
 246 of mesoporous systems in the intrinsic microporosity to obtain hierarchical zeolites [13,75,78] or  
 247 lamellar zeolites such as Ti-MFI [84], Ti-MWW [85] and Ti-FER [86,87]. The synthesis of nanocrystals  
 248 of Ti-zeolites has also appeared as an interesting strategy to increase the specific surface area of these  
 249 materials [88]. The improvement of the textural properties allows the diffusion of bulky substrates.  
 250 However, these materials display more hydrophilicity, which affects their catalytic performance,  
 251 compared to TS-1 [89–91]. For this reason, modifying the hydrophobicity of the catalyst surface could  
 252 enhance the catalytic performance as it has been proposed by some researchers [41,92,93].

258

259

In general, many titanosilicates have been created but only few of them are used in industrial processes such as TS-1, Ti-Beta, Ti-MCM-41, Ti-MCM-48, Ti-SBA-15, Ti-MWW and Ti-MOR. The last two are not presented in this section but the description of these titanosilicates is presented in ANNEX I.

260 The aim of this work is to discuss about the titanosilicates that have been hydrophobically  
261 modified, according to the literature. Our discussion will be focused on the influence of such  
262 modification on their catalytic activity.

263

#### 264 1.1.3.1 TS-1

265 The TS-1 titanosilicate was synthesized by Tamarasso et al. [51] in 1983. TS-1 is an aluminum  
266 free Ti-zeolite categorized as a common medium pore (10-ring pore channels) zeolite with MFI  
267 framework type and Ti atoms introduced in its structure [55]. TS-1 has been employed as one of the  
268 most efficient catalyst in several oxidation processes [94–99]. Reviews about the synthesis and  
269 properties of TS-1 were published by Notari in 1993 [100] and 1996 [50]. TS-1 has been synthesized  
270 by several routes varying the Si and Ti sources as well as the template and mineralizing agent, in  
271 function of their industrial use. These different methodologies were collected in the work of Perego  
272 et al. [101]. However, one of the most common method of synthesis of TS-1 is the hydrothermal  
273 method using tetraethyl orthosilicate (TEOS) as precursor of Si, and different precursors of titanium  
274 such as tetrapropyl orthotitanate (TPOT) or tetrabutyl orthotitanate (TBOT)), with tetrapropyl  
275 ammonium hydroxide (TPAOH) as structure-directing agents (SDA). The preparation of TS-1 often  
276 requires the use of microporous SDAs due to the low synthesis yield [34,51,102]. The maximum  
277 atomic percentages of tetrahedral Ti active sites in the MFI zeolite framework is 2.5% (Ti/Ti+Si) [13].  
278 The methodologies for preparation of TS-1 are focused in obtaining more tetrahedral Ti(IV) active  
279 sites as possible and diminishing the formation of EFW-Ti [14].

280

#### 281 1.1.3.2 Ti-Beta

282 Ti-Beta is a large-pore (12-ring pore channels) Ti-zeolite with BEA framework type and Ti atoms  
283 incorporated in the zeolite structure. Originally, Ti-Beta was described as a titano-aluminosilicate by  
284 Cambor et al. [103]. Aluminum containing Ti-Beta was prepared by conventional hydrothermal  
285 synthesis to introduce Ti directly into the zeolite structure using tetraethylammonium hydroxide  
286 (TEAOH) as SDA. The Ti/Al ratio was around 50 for all samples [103].

287 The presence of Al in the Beta framework produces acid centers which can act as acid/redox  
288 active sites. The selectivity and activity of oxidation reactions was affected by the acidity of the Al-  
289 containing Ti-Beta catalysts. For instance, the selectivity to epoxide decreases in epoxidation of olefins  
290 with the increase of Al [1]. For this reason, Al-free Ti-Beta was synthesized by Cambor et al. using  
291 dealuminated Beta-zeolite as crystallization seeds [104]. These seeds were obtained from Beta zeolites  
292 prepared according to Cambor et al. [105], and then, they were dealuminated by acid treatment using  
293 HNO<sub>3</sub> (60%) at 80°C during 24 h with liquid/solid ratio of 60. The Si/Al ratio was higher than 1 000  
294 [106]. The dealuminated Beta-zeolite seeds were added to a mixture of Si and Ti precursors,  
295 tetraethylammonium hydroxide (TEAOH), H<sub>2</sub>O, and H<sub>2</sub>O<sub>2</sub>. The Si/Al ratio increased over 10 000  
296 [104]. Another study proposed the synthesis of Al-free Ti-Beta by unseeded method in fluoride (F<sup>-</sup>)  
297 medium [37]. A recent method to obtain Al-free Ti-Beta involved the post-grafting of Ti onto  
298 dealuminated Beta. For this purpose, commercial Beta zeolites with specific Si/Al ratio were  
299 dealuminated by acid treatment with HNO<sub>3</sub> and then, Ti atoms were inserted by adding TiCl<sub>4</sub> to a  
300 suspension of dealuminated Beta zeolite in dichloromethane (CH<sub>2</sub>Cl<sub>2</sub>) [39].

301 Ti-Beta is an efficient catalyst for epoxidation of cyclic and long linear alkenes and also cyclic  
302 and branched alkanes [107]. For example, Ti-Beta exhibits better catalytic performance in the  
303 epoxidation of cyclohexene in comparison to TS-1 [108]. However, due to the limitation of the number  
304 of tetrahedral Ti active sites, some alternatives have been developed to improve the Ti content of  
305 these catalysts [38,109–113].

306

#### 307 1.1.3.3 Ti-MCM-41

308 The MCM zeolite with a one-dimensional channel system is a widely studied mesoporous  
309 material due to its interesting structural and textural features. It consists of a hexagonal array of  
310 unidirectional tubular pores. Ti-MCM-41 high surface area (frequently above 1000 m<sup>2</sup>g<sup>-1</sup>) and pore

size (2-10 nm) allow the use of this zeolite as catalyst of a wide range of chemical processes [114,115]. The Ti-MCM-41 with regular pores of 35 Å is an extra-large Ti-zeolite obtained by direct synthesis using tetramethylammonium hydroxide (TMAOH) [79,116]. Important variables such as the OH/SiO<sub>2</sub> ratio and the content of alkali metal cation must be considered to prepare catalysts with Ti active sites in tetrahedral coordination. In absence of alkali cations, an optimum OH/SiO<sub>2</sub> ratio of 0.26 allowed the formation of Ti-MCM-41 with high content of FW-Ti and undetectable EFW-Ti [79]. The pore size of Ti-MCM-41 with high crystallization may be controlled by regulating the temperature of synthesis [117] whereas the Ti-MCM-41 channel diameter can be adjusted by using different surfactant templates [118].

Other modifications of the synthesis of Ti-MCM-41 have been applied to increase the number of Ti active sites. For example, electrostatic assembly of Ti-MCM-41 achieved higher catalytic activity in the liquid-phase oxidation of styrene, methyl methacrylate and 2,6-di-tert-butylphenol [119], post-grafting of titanium atoms to form Ti-MCM-41 based materials [120], synthesis of Ti-MCM-41 by hydrothermal method using supercritical fluid as an extraction medium to remove of SDA [121], and post-synthesis salt solution treatment with alkaline and ammonium salts which increases the tetrahedral Ti and improves the catalytic activity and selectivity in the epoxidation of cyclohexene [122], among others.

The mesoporous Ti-MCM-41 are important in the reactions of bulky substrates. For example, Ti-MCM-41 showed higher catalytic activity for cyclooctene and cyclododecene epoxidation than TS-1, Ti-Beta and Ti-MWW [123]. Ti-MCM-41 has been used in the phenol and 2,3,6-trimethylphenol hydroxylation and styrene epoxidation [124], propylene epoxidation [125–127] and cyclohexene epoxidation [128]. Also, Ti-MCM-41 and MCM-41 has been used as support of catalysts for oxidation reactions [129,130].

#### 1.1.3.4 Ti-MCM-48

The MCM 41 and MCM 48, and other structures are members of a family of mesoporous molecular sieves denoted M41S with high importance into the catalysis and materials fields. The MCM-48 zeolite framework has a cubic array and a 3-dimensional channel system [80,131]. MCM-48 displays catalytic advantages over a MCM-41 due to the 3-dimensional pore system and its better resistance to obstruction by strange materials [80].

A study about the stabilization of the M41S was developed by Tatsumi *et al.*, in 1998. It is known that the MCM-41 and MCM-48 molecular structures collapsed by mechanical compression due to the hydrolysis of Si-O-Si bonds in presence of water adsorbed into the sieve. The trimethylsilylation was carried out to modify the hydrophobicity of these materials and improved their stability in water [132]. The Ti-MCM-48 was synthesized by a one-stage hydrolysis method and two-stage method using a solution of tetraethylorthosilicate (TEOS) and TBOT as precursors and *n*-heptadecyltrimethylammonium hydroxide and cetyltrimethylammonium chloride [80]. Also, Ti-MCM-48 was prepared using the cetyltrimethylammonium bromide as surfactant [133]. The Ti-MCM-48 has been employed as catalyst in the epoxidation of 2-buten-1-ol [134], methyl allyl chloride with H<sub>2</sub>O<sub>2</sub> [135], allylic compounds with H<sub>2</sub>O<sub>2</sub> [136], crotyl alcohol [137], photocatalytic degradation of rhodamine B [138] and in the removal of Cd(II) by adsorption [139]. CdS has been incorporated in the Ti-MCM-48 material for photocatalytic decomposition of water [140] and solar hydrogen generation [141]. Metals such as Fe [142] and Pd [143] and oxides such as CuO [144] and Copper porphyrin [145] have been impregnated in Ti-MCM-48 structure for different applications. Also, Ti-MCM-48 has been used as support of Au for the vapor-phase propylene epoxidation [125].

356 356

#### 1.1.3.5 Ti-SBA-15

The SBA-15 structure has pores with diameters between 50 and 300 Å, a surface area of 600-1000 m<sup>2</sup>g<sup>-1</sup> and pore volumes of 0.6-1.3 cm<sup>3</sup>g<sup>-1</sup>. The SBA-15 zeolite was synthesized using triblock copolymers as a template under acid conditions. The resulting SBA-15 contained high silanol groups on the surface which then offer reactive sites for post-functionalization. Ti was introduced into the

362 SBA framework by both hydrothermal and post-grafting methods. These methods produced  
363 catalysts with high catalytic activity and high surface area capable of oxidize molecules with large  
364 size [146,147].

365 Ti-SBA-15 is an ultra-large mesoporous Ti-zeolite similar to Ti-MCM-41, except Ti-SBA-15 has a  
366 one-dimensional system with hexagonal array, but the main channels are connected by micropores  
367 [148]. Fluoride medium has been applied in the synthesis of Ti-SBA to accelerate the hydrolysis rate  
368 of Si precursors. The catalytic activity and selectivity of this Ti-SBA was higher in the styrene  
369 epoxidation [149].

370 The Ti-SBA has been used as catalyst of several reactions such as oxidation of methyl-propyl-  
371 thioether using  $H_2O_2$  as oxidant [150], alkene epoxidation [148], hydrodesulfurization [151] and  
372 hydrogenation of tetralin [152]. Among other applications, Ti-SBA-15 has been applied as support  
373 for different metals such as NiMoW and CoMoW [153], and CoMo [154] for hydrodesulfurization  
374 reactions, ionic liquids with Brønsted-Lewis acidity also were deposited on Ti-SBA-15 by  
375 impregnation method and then were used as catalyst for esterification of acetic acid [155].

#### 376 1.1.4 Titanosilicates without zeolite frameworks (Ti-SiO<sub>2</sub>)

377 The discovery of TS-1 represents a breakthrough in the oxidation of organic compounds with  
378 solid catalysts under mild conditions. However, due to the mass-transfer limitations in microporous  
379 TS-1, several large and ultra-large Ti-zeolites have been synthesized. There is an increasing interest  
380 in the fabrication of titanosilicates with even larger pore sizes and higher number of Ti active sites  
381 that can be used with bulkier substrates. In this way, amorphous titanosilicates with no zeolitic  
382 framework (Ti-SiO<sub>2</sub>), also called titania-silica (TiO<sub>2</sub>-SiO<sub>2</sub>) mixed oxides, have been prepared for  
383 oxidation reactions [3,156].

384 The first Ti-SiO<sub>2</sub> was synthesized by Shell researchers in 1971 [157] and they were used as catalyst  
385 of propylene epoxidation with alkylhydroperoxides as oxidants. The active sites of this type of  
386 catalysts are tetrahedral Ti isolated by O-Si fragments. The formation of Ti-O-Si bonds renders  
387 chemical stability to the Ti-SiO<sub>2</sub> catalysts and prevents leaching problems [158]. Also, the dispersion  
388 of titanium into the silica matrix generates Lewis acid sites. The catalyst acidity increases with the  
389 higher dispersion of titanium in the silica matrix [159].

390 Ti-SiO<sub>2</sub> catalysts can be prepared by sol-gel method. The first attempts to use sol-gel to  
391 synthesize Ti-SiO<sub>2</sub> for cyclohexene and cyclooctene epoxidation with  $H_2O_2$  were reported by  
392 Neumann *et al.* in 1993. Ti-SiO<sub>2</sub> were efficient in the olefin's epoxidation after 20 hours [160]. The  
393 influence of the sol-gel preparation method and drying conditions on the structural and chemical  
394 properties of Ti-SiO<sub>2</sub> were studied by Hutter *et al.* in 1990s [3]. It has been demonstrated that by an  
395 appropriate preparation and drying conditions, an amorphous material with high surface area and  
396 outstanding titania dispersion (20 %wt TiO<sub>2</sub>) in silica matrix can be achieved [3]. In a second part of  
397 their investigation, Hutter *et al.* reported about the catalytic properties of Ti-SiO<sub>2</sub> for epoxidation of  
398 olefins [161]. High catalytic activity and selectivity can be expected for Ti-SiO<sub>2</sub> with mesoporous  
399 structure regarding the epoxidation of linear or cyclic olefins and electron-deficient olefin such as  $\alpha$ -  
400 isophorone which are difficult to epoxidize [158].

401 The remarkable catalytic activity of Ti-SiO<sub>2</sub> is related with their textural and structural properties  
402 (mesoporosity and high dispersion of Ti). Therefore, the Ti content has an influence on the structural  
403 and catalytic properties of Ti-SiO<sub>2</sub> catalysts and consequently in the accessibility of the reactants on  
404 the Ti active sites in tetrahedral coordination [3]. Initially, it was determined that an increase of the  
405 content of Ti from 2 to 20 wt% TiO<sub>2</sub> increased the Si-O-Ti heteroconnectivity, so a maximum of 20  
406 wt% TiO<sub>2</sub> was appropriate for epoxidation catalysts. An increase to 30 wt% TiO<sub>2</sub> leads to agglomerates  
407 of TiO<sub>2</sub>, bad dispersion of Ti and lower catalytic activity. Another relevant factor that regulates the  
408 textural properties is the aging of the wet sol-gel which strengthens the gel network and thereby  
409 preserves the porous network of the dried gel [162].

410 Ti-SiO<sub>2</sub> catalysts are commonly used for olefin isomerization [163–165], aromatics amination  
411 [163], alcohols dehydration [166], aromatics dealkylation [166] and selective oxidation [46,47,175–

178,167–174]. Since the first synthesis of Ti-SiO<sub>2</sub>, several researchers focused on the study of this group of materials. A review, published by Davis and Liu in 1997, summarizes valuable information about the microstructural characteristics and catalytic activity of Ti-SiO<sub>2</sub> catalysts [179]. Other applications of Ti-SiO<sub>2</sub> in the catalytic field can be found in the literature [167,169,180–185].

A drawback of Ti-SiO<sub>2</sub> catalysts is their strong hydrophilic character caused by the silanol groups present on the surface. This property limits their use in aqueous media or in presence of hydrogen peroxide as oxidant. The deactivation of Ti active sites in tetrahedral coordination can be decreased by hydrophobization of the surface. Therefore, some researchers have studied the influence of hydrophobic modification of the catalyst surface on their catalytic activity [45,172,173,186,187].

## 1.2 Description of the hydrophobization methodologies and techniques for measuring the hydrophobicity of titanosilicates.

### 1.2.1 Hydrophobicity basics

The term hydrophobicity/philicity refers to the affinity that exists between a solid surface and water. A hydrophobic surface can be defined similarly as a hydrophobic substance. Nonpolar substances are hydrophobic and have low solubility in water at room temperature. The accumulation of the nonpolar molecules in aqueous media produces a high cohesive energy density of water that decreases the interface between the nonpolar substance and water, explaining the hydrophobic effect. Therefore, to transfer nonpolar molecules into a aqueous media, the enormously stable hydrogen bond among water molecules must be disrupted [32,188]. A summary of intermolecular interactions is presented in ANNEX II.

Although there are some analytical techniques that provide information about hydrophobicity of flat surfaces, there is not a specific technique for porous solid surfaces. The hydrophobic effect in solids is related to the absence of interfacial interactions with water or similar dipolar and protic molecules. And more exactly, a better definition can be achieved contemplating the possible forces between a solid surface and an adsorbate molecule. The interactions of water with a solid surface are commonly generated from specific surface sites such as functional groups that can act as Brønsted or Lewis acids or bases (Table 3) [32].

**Table 3** Functional groups that affect the hydrophilic character of solid porous surfaces [32].

Functional group		Occurrence
Hydroxyl	-OH	Oxides, hydroxides
Carboxyl	-COOH	Carbons
Carbonyl	-C=O	Carbons
Ether	-O-	Oxides, carbons
	Ionic species (i.e., H <sup>+</sup> , Na <sup>+</sup> , Mg <sup>+2</sup> , Cl <sup>-</sup> )	Ion exchanger

440 440

The mutual molecular interactions that affect the wettability of a solid surface are reflected in a macroscopic parameter known as contact angle (CA) formed between the solid phase boundary and the liquid phase [189]. It is possible to quantify the hydrophobicity of the solid surface as a function of the CA. However, there are some limitations to measure the CA of rough solid surfaces or surfaces with defects such as functional groups (i.e., silanol groups) [32].

It should be noted that hydrophobicity/hydrophilicity is a relevant property that must be considered for the synthesis of porous solid catalysts. The catalytic performance of a solid catalyst is not only associated to the active sites but is also influenced by the catalyst wettability which affects the adsorption and desorption processes and mass transfer on the surface (Figure 3). Adjustment of the surface hydrophobicity could enhance the activity, selectivity and lifetime of catalysts [190]. Thus, it is necessary to inquire into the concepts of hydrophobicity to apply measuring techniques in the correct form.

453 453

454 **Figure 3** Reaction process over a solid catalyst (R= reactants, P=products). Taken from [190]

## 455 1.2.2 Methodologies for hydrophobization of titanosilicates

456 The catalytic activity of titanosilicates depends not only on the dispersion of the tetrahedral Ti  
 457 active sites, but also on the hydrophobic character of the material [191]. Two main strategies have  
 458 been used to modify the hydrophobicity of titanosilicates. The first strategy is the modification of the  
 459 hydrophobicity by the control of the silanol surface density. It is known that free-defect siliceous  
 460 surfaces formed by Si-O-Si bonds are hydrophobic [63], whereas hydroxyl groups (Si-OH) and  
 461 bridging hydroxyl groups (i.e., Si-OH-Ti, Si-OH-Al) are hydrophilic [64]. The hydrophilic character  
 462 of these materials increases while the surface density of silanol groups increases, thus they adsorb  
 463 more water [65].

464 The silanol surface density can be adjusted by improving the crystallization of the material, and  
 465 by synthesizing the material in fluoride (F<sup>-</sup>) medium instead of OH<sup>-</sup> medium. Highly crystallized TS-  
 466 1 has less Si-OH terminal groups and is more hydrophobic [34]. Some heteroatom-substituted MFI  
 467 zeolites (M-MFI), including Ti-zeolites, were synthesized in fluoride medium (F<sup>-</sup>) using hydrofluoric  
 468 acid (HF) with TPAOH as structure directing agent. Adsorption isotherms showed that M-MFI  
 469 zeolites synthesized in F<sup>-</sup> medium adsorbed 100 times less water than the analogous materials  
 470 synthesized in OH<sup>-</sup> medium. Also, the number of Si-OH groups decreased linearly with the  
 471 increasing HF/TPAOH ratio [192]. Al-free Ti-Beta was another Ti-zeolite modified hydrophobically  
 472 by synthesis in F<sup>-</sup> medium, and a lower content of Si-OH was detected compared to the conventional  
 473 Ti-Beta [38].

474 The second strategy applied to modify the hydrophobicity of the titanosilicates is the  
 475 functionalization with organic groups both on the catalyst external surface and on the internal  
 476 porosity where the active sites are located [193]. The functionalization of the catalyst surface has been  
 477 carried out by "post-grafting" of organic groups [93] and by "one-pot functionalization" [194,195].  
 478 For example, Ti-SiO<sub>2</sub> functionalized with poly(methylhydrosiloxane) (PMHS) by post-grafting was  
 479 more hydrophobic than conventional Ti/SiO<sub>2</sub> [49]. In the same way, Ti-MCM-41 functionalized by  
 480 the one-pot procedure with organosilanes exhibited lower silanol surface density and a strong  
 481 hydrophobic character [40]. Hydrophobic environments, both on the external and internal surface  
 482 could have important consequences on the reactivity of porous catalysts [65].

483

## 484 1.2.2.1 Control of silanol density

485 The content of silanol defects on titanosilicates can be adjusted by the control of the  
 486 crystallization process. This crystallization process of these materials is complex, and it is affected by  
 487 some synthesis parameters such as the silica source, templates, and SDAs. Crystallization of  
 488 titanosilicates is more difficult than crystallization of aluminosilicates because Ti<sup>4+</sup> displays a weaker  
 489 structure-directing role compared to Al<sup>3+</sup>. In addition, the Ti-O bond (1.80 Å) is longer than the Si-O  
 490 bond (1.61 Å), which distorts the structure around Ti and results in a slow insertion of Ti into the  
 491 zeolite framework and in the formation of undesired phases. These facts make more complex the  
 492 isomorphous substitution of Si<sup>4+</sup> by Ti<sup>4+</sup> compared to that of Al<sup>3+</sup> by Ti<sup>4+</sup>. The isomorphous substitution  
 493 is influenced by the crystallization of titanosilicates. An effective crystallization-mediating agent was  
 494 proved as an alternative to improve the crystallization of TS-1. The characterization of the TS-1

495 obtained by this method showed that the insertion of titanium into the framework was improved and  
 496 the silanol defects decreased [34].

497 On the other hand, the presence of silica networks in microporous, mesoporous, and amorphous  
 498 materials strengthen the coordination of heteroatoms united by oxygen which prevent hydrolysis  
 499 and leaching. Hydrophobic structures in silica surface avoid the hydrolysis of Si-O-Si and Si-O-M  
 500 bonds since they disturb the formation of long water phases near them, preventing the deactivation  
 501 of active sites in aqueous media. Hydrophobic structures also avoid the deactivation of active sites  
 502 produced by water adsorption. Silica and metal oxide networks (Si-O-M) are present in Brønsted and  
 503 Lewis acid oxides [65].

504 In the case of aluminosilicates, the low silicious zeolites (Si/Al= 1-2) possess high amounts of  
 505  $\text{AlO}_4$  units and Si-O-Al bridges, so they are more hydrophilic than high silicious zeolites (Si/Al= 10-  
 506  $\infty$ ) [196]. The Al-O bond is more polar (40% covalent and 60% ionic bond) than the Si-O bond (100%  
 507 covalent bond) and thus, strong interactions with water are produced [197]. On the other hand,  
 508 silanol groups and bridging hydroxyl groups form hydrophilic domains into the silica framework  
 509 [64] and these polar hydroxyl groups adsorb water. Thus, the amount of water adsorbed is related to  
 510 the Al content in zeolites. For instance, the water adsorption of ZSM-5 [198,199], Beta [64], MCM-41  
 511 [200], and Ti-Beta [38] gradually decreased with the increase of Si/Al ratio.

512 In this context, the combination of dealumination and post-insertion of heteroatoms can produce  
 513 materials with higher hydrophobicity [39]. According to the IR characterization of dealuminated Ti-  
 514 Beta, a higher content of Si-OH groups was detected with the decrease of Al content [104]. In contrast,  
 515 when titanium heteroatoms were incorporated into dealuminated Beta zeolite, the density of isolated  
 516 silanol groups decreased whereas silanol nests ( $\text{SiOH}$ )<sub>4</sub> decreased in Beta zeolites with less amount  
 517 of Al compared with those with high Al content [39]. As shown in Figure 4, the dealumination process  
 518 creates vacancy defects which result in the formation of silanol nests that consequently increases the  
 519 hydrophilicity of these materials. The incorporation of Ti atoms in these vacancy defects decreases  
 520 the concentration of silanol nests.

521 521

522

Figure 4 Dealumination and post-incorporation of Ti to prepare Ti-Beta.

523 Al-free Ti-Beta can also be obtained by indirect ways, one of them is the dealumination of Ti-  
 524 Beta. Another way is the synthesis of Ti-Beta using dealuminated seeds of Beta zeolite, and the last  
 525 one is the post-synthetic modification of commercial Beta zeolite (see section 1.1.3.2).

526 A direct way to synthesize hydrophobic Al-free Ti-Beta is using fluoride ( $F^-$ ) medium instead of  
 527 aqueous ( $OH^-$ ) medium. The  $F^-$  medium prevents the formation of anionic framework vacancy defects  
 528 since the cationic charges of SDAs employed in the synthesis are counterbalanced by  $F^-$  forming  
 529 strong ion-pairs [201,202]. As shown in Figure 5, when  $OH^-$  anions are used in the synthesis, anionic  
 530 framework vacancy defects are produced and after removal of SDA cations, silanol nests are formed  
 531 in zeolite framework increasing the hydrophilicity of the material.

532 532

533 533

534 **Figure 5** Preparation of zeolites in fluoride medium and aqueous medium. Adapted from [202].

535 As already mentioned, the silanol surface density of titanosilicates could be modified through  
 536 the presence of  $F^-$  ions during synthesis. However, the presence of  $F^-$  ions reduces the incorporation  
 537 of Ti atoms into the final material. Therefore, determining the optimal concentration of  $F^-$  ions able to  
 538 decrease the silanol surface density while maintaining an effective incorporation of heteroatoms in  
 539 the titanosilicates is essential. Indeed, the ratio between HF/SDA (TPAOH) was optimized by  
 540 Bregante et al. for zeolitic materials with MFI structure (Silicalite-1) where heteroatoms Nb, Ta, and  
 541 Ti were inserted. The relative silanol density was quantified using IR spectroscopy. The authors  
 542 normalized the area of  $\nu(Si-OH)$  relative to that of the  $\nu(Si-O-Si)$ , observing a linearly  
 543 decrement as the HF/TPAOH ratio ( $x$ ) increases. With  $x < 1$ , the relative silanol density decreased by  
 544 4-8-fold, whereas for  $x = 1.5$ , the relative silanol density decreased 30-100 times compared to materials  
 545 synthesized in  $OH^-$  medium. For  $x > 1.5$  the relative silanol density was undetectable. The formation  
 546 of the strong ion-pairs between TPAOH cation ( $TPA^+$ ) and  $F^-$  is reversible and the concentrations of  
 547 species are defined by the equilibrium. Finally, water adsorption experiments of TS-1 showed that  
 548 TS-1 synthesized in  $F^-$  medium stabilized  $\sim 5$  water molecules at vapor pressure at 293 K and adsorbed  
 549 7-100 times less water than TS-1 synthesized in  $OH^-$  medium. The number of water molecules  
 550 stabilized by Ti was calculated from the difference between the  $H_2O$  uptake of TS-1 and silicalite-1,  
 551 which is then normalized by the number of Ti atoms [192].

552

#### 553 1.2.2.2 Organic functionalization

554 Organic functionalization of titanosilicates through one-pot and post-grafting method were  
 555 applied to obtain more hydrophobic catalysts. The silanol density in functionalized materials was  
 556 lower than in the non-functionalized ones [28,40,41,45,48,49,203]. This low density was mainly

557 attributed to the substitution of Si-OH groups by organic moieties and it was confirmed by IR  
558 spectroscopy and  $^{29}\text{Si}$  NMR analysis [40,41,45,49].

559 The effect of the organic functionalization on the catalytic activity was in some cases either  
560 positive for Ti-SiO<sub>2</sub> [48] and Ti/SiO<sub>2</sub> [49], or negative for Ti-Beta [6] or non-significant for TS-1 [6] and  
561 Ti/SiO<sub>2</sub> [204]. A possible explanation about the different catalytic effects was that the post-grafting  
562 can also modify the structure and textural properties of catalysts, and the nature of active sites [45].

563 The principal difference between post-grafting and one-pot methods lies on the Ti dispersion.  
564 According to XPS and DRUV-Vis analysis, titanosilicates functionalized by the one-pot method  
565 exhibited lower Ti dispersion. One-pot functionalization method is faster and it can be controlled by  
566 the chemistry of precursors [45]. Ti speciation was not affected by post-grafting in most of the cases.  
567 Regarding the textural properties, both functionalization procedures diminished the specific surface  
568 area and pore size. This difference in textural properties can affect the catalytic performance of  
569 functionalized catalysts [48].

570 Ti dispersion on one-pot synthesis was enhanced using aerosol-assisted sol-gel. With this  
571 method, not only the Ti dispersion but also the organic functionalization and textural properties were  
572 controlled [11]. The effective dispersion of Ti with this method was attributed to the fast drying of  
573 the atomized mixture of precursors, which produces the quenching of kinetic condensation and leads  
574 to the formation of stable solid phases with homogeneous compositions [205].

### 575 1.2.3 Determination of hydrophobicity of titanosilicates

576 Some analytical techniques applied for the characterization of the hydrophobic character of  
577 porous solids will be discussed in this section. Due to the absence of a precise definition of the term  
578 hydrophobicity and its origin, the analytical techniques applied to characterize this property in solids  
579 differ particularly regarding the experimental method and the physical/chemical properties  
580 considered for the evaluation of the porous solid surface. In fact, analytical techniques have ranked  
581 a given set of porous solids according to their hydrophobic character, but a quantitative assessment,  
582 considering the theory remains a challenge. Also, it is important to keep in mind that the conditions  
583 under which the experimental analysis is carried out not always correspond to the conditions in the  
584 application, especially in the case of catalysts. In addition, the applicability of the characterization  
585 techniques will depend on each type of porous solids [32].

#### 586 1.2.3.1 Contact Angle Measurement

587 As already mentioned in the section 1.2.1, the contact angle (CA) is a known technique that  
588 allows the characterization of surface wettability. The CA is related to the lowest state of the energy  
589 that characterizes a three-phase system (solid-liquid-gas). This experimental thermodynamic  
590 property corresponds to the observed angle at the contact line among these three phases. This angle  
591 is bounded by the tangent to the liquid-fluid interface and the tangent to the solid surface [206]. The  
592 CA is computed using the Young equation [207]. The Young's equation associates several terms as  
593 the solid surface energy  $\gamma_{sv}$ , the solid-liquid surface tension  $\gamma_{ls}$ , the liquid surface tension  $\gamma_{lv}$  and  
594 the cosine of the contact angle  $\theta$ . As a soon as a resting drop reaches the mechanical equilibrium on  
595 a plane solid surface, these three forces are balanced and can be described as expressed in Eq (1) [208].  
596

$$\gamma_{sv} = \gamma_{ls} + \gamma_{lv} \cos \theta \quad (1)$$

597 For a drop with a certain radius of curvature, the CA equals the Young contact angle as long as  
598 this radius is larger than the nanometric scale. The Young contact angle is related to the equilibrium  
599 state reached by a drop on an ideal solid. However, a correction term needs to be applied for drops  
600 with smaller radii of curvature [206,209–211]. The ideal determination of the CA may encounter some  
601 difficulties, starting even before the measurements with the correct preparation of the solid surface  
602 and then during the measurements with the control of the equilibrium conditions. These challenges  
603 render the experimental determination not always feasible [206].

604 Contact angles are principally reported as static and dynamic. On the one hand, if the three-  
605 phase boundary is not moving and the droplet is sitting on the surface, measurements of static contact  
606 angles are obtained. On the other hand, if the three-phase boundary moves, measurements of  
607 dynamic contact angles are registered. These angles are defined as advancing (when the droplet front  
608 is advancing) and receding (when the droplet front is receding). The term hysteresis referred to  
609 contact angles is then established as the comparison between these two angles (advancing and  
610 receding). Experimental approaches like sessile drop and/or captive bubble [212–216] are preferred  
611 methods for the measurement of contact angles at ambient conditions on flat surfaces under different  
612 pressure and temperature conditions [217].

613 Several factors affect contact angles including deformation, roughness, contamination, and  
614 surface geometry. Thus, it is not uncommon to find more than one contact angle value reported for a  
615 certain system, taking into account all the variables that affect the experimental determination of the  
616 CA [206]. Furthermore, in most natural materials the effective contact angle observed at larger scales  
617 is influenced by the surface roughness detected at the nanometer scale. Regarding the porous media  
618 as the closest approach to understand the wettability of porous solids as titanosilicates, some  
619 challenges are identified. In general, contact angles in porous media can be not only variable  
620 throughout the pore space, but also scale-dependent and hysteretic owing to the presence of local  
621 surface roughness enhanced by variations in mineralogy and coating. However, it has been possible  
622 to determine geometrical contact angle values in the pore space. Some of the more common  
623 measurements include automated algorithms [218,219] or visual observation [220,221]. Other  
624 methods analyze the solid and fluid interfaces through the deficit curvature between them [222].  
625 Recently, 3D images of fluids in the pore space generated by mCT (micro-computed X-ray  
626 tomography) were used for geometrical analysis of contact angles [223,224]. Nevertheless, the  
627 interpretation of these measurements are still difficult, regarding the broad range of variation found  
628 in the contact angle values obtained by this technique [225,226]. In fact, the scale of the pore size  
629 distribution of titanosilicates, which can vary from 5 Å to ~100 nm, is even smaller compared to the  
630 roughness scale range (~200 µm) reached through the most sophisticated techniques for determining  
631 the contact angle in porous media. Thus, the information that could be eventually obtained from the  
632 contact angle of titanosilicates does not adequately describe the whole hydrophilic-hydrophobic  
633 nature of the study material.

634

#### 635 1.2.3.2 Thermogravimetric Analysis (TGA)

636 Thermogravimetric Analysis (TGA) measures the mass variation of a sample while it is heated,  
637 cooled, or isothermally maintained under a defined atmosphere, inert or oxidizing. The analysis can  
638 be carried out at constant temperature or constant heating rate. A typical TGA curve shows the mass  
639 loss steps generally associated to the loss of volatile components, carbon black combustion, polymer  
640 decomposition, and final residues due to the temperature changes. This method permits the study of  
641 materials decomposition and their products, drawing conclusions about their individual components  
642 [227].

643 TGA is used to determine the water adsorption capacity that is the quotient between the mass  
644 loss due to the water desorption by the mass of dry sorbent [228]. In the hydrophobicity studies, TGA  
645 is a common analytical technique used for the determination of water affinity of solids or for the  
646 quantification of hydroxyl groups on the surface that is an indirect way to quantify the water affinity  
647 of solid surfaces [229]. However, the sample preparation and storage could have an impact over the  
648 measurement of physisorbed water and lead to imprecise conclusions about the  
649 hydrophobicity/philicity of a material. Additionally, comparison of the hydrophobicity of materials  
650 must be performed carefully since the measurement of physisorbed water is expressed per gram of  
651 sample, so materials with higher surface areas will display a higher amount of physisorbed water per  
652 gram of sample. The comparison is clearer when physisorbed water is normalized by the specific  
653 surface area.

654 One way to quantify the hydrophobicity of the surface of microporous solids is the  
 655 “hydrophobicity index” (HI), which was firstly introduced by Anderson and Klinowski [230]. This  
 656 model is based on water adsorption and is not useful for characterization of zeolitic sorbent. The mass  
 657 losses at each temperature range are measured by TGA, and the HI is determined according to  
 658 Equation (2).

$$HI = \frac{\text{Mass loss up to } 150\text{ }^{\circ}\text{C}}{\text{Mass loss up to } 400\text{ }^{\circ}\text{C}} \quad (2)$$

659 If HI=1, the material is considered hydrophobic, and when HI=0, is a hydrophilic material.  
 660 Another definition of HI was given by Giaya et al. as shown in Equation (3):

$$HI = \frac{V_t - V_{>150\text{ }^{\circ}\text{C}}}{V_t} \quad (3)$$

661 where  $V_t$  is the total pore volume of the sorbent and  $V_{>150\text{ }^{\circ}\text{C}}$  is the volume of water desorbed  
 662 at temperature above 150 °C. If HI=1, the material is presented as very hydrophobic, and when HI=0,  
 663 the material is presented as very hydrophilic [231].

664 TGA measurements provide information about the water adsorbed physically, but not  
 665 necessarily about the affinity. As Mueller et al. stated in 2003, the water mass loss at temperatures  
 666 below 120 °C was attributed to the loss of water adsorbed physically, but this value is not related to  
 667 the water affinity of the material surface. In fact, Mueller found that the presence of OH groups on  
 668 the SiO<sub>2</sub> surface can be measured in the temperature range of 120-800°C, and the OH content was  
 669 normalized to the specific surface area to be able to compare the OH/m<sup>2</sup> of each material [232].

670 It is actually a challenge to distinguish between adsorbed water and actual hydroxyl surface  
 671 density, that is, distinguishing between dehydration and dihydroxylation [233]. For this, an  
 672 alternative to measure the actual amount of water that a sample contains was proposed by Lin et al.  
 673 In this study TG analysis were carried out starting from samples of Ti-MCM-41 Ti-zeolite saturated  
 674 with NH<sub>4</sub>Cl solution to guarantee the maximum level of water adsorption. The total number of  
 675 molecules of water adsorbed on the surface was determined from the mass loss between 25 and 150  
 676 °C [195]. In this procedure the authors controlled the ambient conditions of the sample before TGA  
 677 experiments, which allowed to compare the samples independently of the synthesis and storage  
 678 conditions.

#### 679 1.2.3.3 Infrared Spectroscopy (IR)

680 Infrared Spectroscopy (IR) is a common technique applied to characterize solid catalysts. It can  
 681 be used as a direct way to study the composition of solid surfaces or as an indirect way providing  
 682 information about the interactions between the surface and adsorbate [229].

684 IR is a popular technique to measure the affinity of water on solids. With IR spectroscopy, the  
 685 polar (e.g. OH) or non-polar groups of the solid surface can be directly quantified, providing an idea  
 686 of the polarity of the surface [234]. Infrared spectra offer information about the types of sorbed water  
 687 molecules that are identified through the measurement of the frequency of the corresponding IR  
 688 peaks. The intensity of absorption band is used to measure the amount of water sorbed [228].

689 In comparison with TGA, IR spectroscopy provides more information about the distinction  
 690 between physically adsorbed and chemically bound water. In fact, when IR spectra are analyzed the  
 691 water deformation band and the hydroxyl stretching vibration do not overlap; nevertheless, water -  
 692 OHs contribute to the intensity of the -OH stretching vibration, which entangles the separation  
 693 between inner and surface hydroxyls [235]. One of the characteristic bands of the IR spectrum of silica  
 694 is related to the presence of -OH groups at 3750 cm<sup>-1</sup>, which is assigned to isolated -OH groups. A  
 695 close-lying band (a tail) formed by the weakly H-bonded -OH groups, appears in the 3600-3750 cm<sup>-1</sup>  
 696 region. The band of strongly H-bonded -OH groups and/or desorbed water appears in the 3400-  
 697 3500 cm<sup>-1</sup> range. The water -OH groups band appears at 1630 cm<sup>-1</sup> (water deformation) and  
 698 contributes to the bands in this region [236–238]. In order to quantify the hydrophobicity of metal-  
 699 substituted zeolites, the silanol IR signals are usually normalized by the band of  $\nu(\text{Si-O-Si})$  at 1990  
 700 and 1865 cm<sup>-1</sup> (assuming this band is constant in the compared materials) [39,239].

In the specific case of titanosilicates, the IR spectra in the OH region displays two intense bands at about 3740 and 4550  $\text{cm}^{-1}$  corresponding to terminal Si-OH and hydrogen-bonded silanol groups at defect sites, respectively [240–242]. For titanosilicates that have been functionalized by post-grafting, the silanol band intensity decreases since the silane binds to surface -OH groups producing Si-O bonds. The C-H vibrational frequency appears after functionalization with organosilane groups [243,244]. C-H stretching and bending vibration bands that reflect the incorporation of alkyl groups appears at 2850-2985 and around 1460  $\text{cm}^{-1}$  [243]. Thus, the lower intensity of the silane band can be used as an indicator of increase of hydrophobicity due to the functionalization success [242]. Additionally, the presence of Si-CH<sub>3</sub> at 1279  $\text{cm}^{-1}$  [45], Si-CH<sub>2</sub> at 1410  $\text{cm}^{-1}$  [245] as well as Si-C, Si-CH<sub>2</sub>-CH<sub>3</sub> are also indicatives of functionalization. Furthermore, the IR analysis of titanosilicates shows the characteristic bands at 1082 and 802  $\text{cm}^{-1}$  attributed to the asymmetric and symmetric stretching vibration of Si-O-Si [244] and the Si-OH band that appears at 950  $\text{cm}^{-1}$  titanosilicates [162].

#### 1.2.3.4 Adsorption Isotherms

Information about the affinity of the surface for a specific compound or in general properties related with the surface can be analyzed with the application of adsorption techniques. The adsorption from the gas phase on materials has been employed as a tool to evaluate the affinity for water [229].

Water affinity can be understood by recording the water adsorption isotherms. A hydrophobic material displays low affinity for water and low water adsorption capacity. In contrast, a hydrophilic material displays high affinity for water, but does not necessarily exhibit a high water adsorption capacity since the latter depends on the pore volume [228]. Therefore, to know if a material is more hydrophobic or hydrophilic, it is necessary to determine the amount of adsorbed water per unit area or mass in the range of low relative pressures [246]. In fact, the measurement of water adsorption capacity at higher relative pressures does not provide information about water affinity since the adsorbate–adsorbate interactions result in a multilayer adsorption and/or pore condensation. To solve this drawback, the water adsorption capacity must be analyzed at low loading (low amount of water adsorbed), without surpassing the monolayer adsorption, to minimize the influence of adsorbate–adsorbate interactions. Also, it is important to consider that using water as adsorbent, a defined monolayer is not easy to obtain and the presence of highly polar sites or acidic sites could increase the local water concentration due to hydrogen bonding. Consequently, it is better to compare materials of the same nature under similar conditions [32].

The hydrophobicity of sorbents has been classified according to the International Union of Pure and Applied Chemistry (IUPAC). This assignation is based on the type of the adsorption isotherm. As shown in Figure 6, there are some curves characteristic of hydrophilic and hydrophobic materials.

For instance, the type I isotherm is assigned to a highly hydrophilic material, the type II isotherm corresponds to a hydrophilic material, the type III isotherm represents a hydrophobic/ low hydrophilic material with weak sorbent–water interactions, the type IV isotherm represents a hydrophilic material, the type V isotherm is associated to a hydrophobic/low hydrophilic material with weak sorbent–water interactions, the type VI isotherm corresponds to a hydrophilic material with multiple sorbent–water interactions and stepwise sorption, and the type VII isotherm is characteristic of a very hydrophobic material [228].

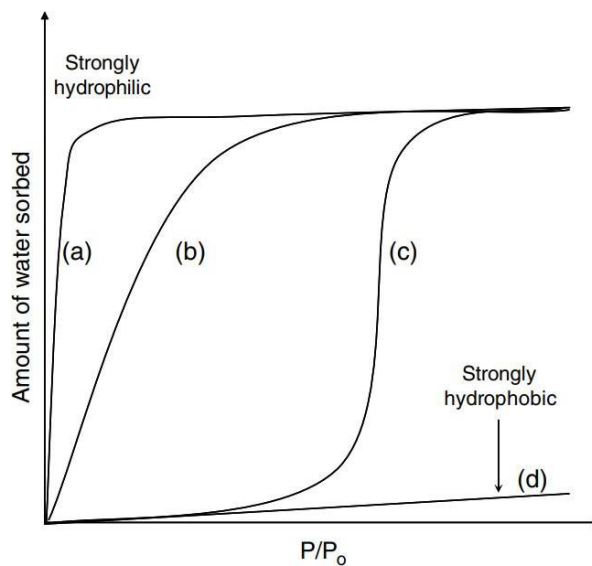

Figure 7 illustrates three water adsorption isotherms of zeolitic materials with different hydrophobicity degrees and with the same pore volume [247]. Curve (a) is a type I isotherm in which the sorption equilibrium in the material is reached after the adsorption of high amount of water at very low relative pressures ( $P/P_0$ ), curve (b) is also a type I isotherm in which the sorption equilibrium is reached at higher  $P/P_0$ , the curve (c) corresponds to a type V isotherm where just a small amount of water is adsorbed at low  $P/P_0$  until the sorption capacity is reached, this is a hydrophobic or weakly hydrophilic solid, and curve (d) represents a type VII isotherm where a very small amount of water is adsorbed in all range of relative pressures, this material is considered highly hydrophobic.

751 According to the adsorption isotherms of materials (a) and (b) at low loading, the material with  
 752 steeper slope is defined as more hydrophilic [228,247].  
 753

754  
 755 **Figure 6** Hydrophobicity of materials based of adsorption isotherms classified according to IUPAC.  
 756 Taken of Ref. [228].

757

758  
 759 **Figure 7** Water adsorption isotherms for ideally hydrophobic and hydrophilic zeolitic materials  
 760 normalized to pore volume. Adapted from Ref. [228].

761 SiWeitkamp et al. used the HI of zeolites for multicomponent sorption based on a competitive  
762 sorption between hydrocarbon and water to quantify the hydrophobicity. The HI is calculated by the  
763 (4).

$$HI = \frac{X_{\text{Hydrocarbon}}}{X_{\text{Water}}} \quad (4)$$

764 where X is the content of molecules adsorbed. A higher HI means a higher adsorption of  
765 hydrocarbon compared to water, thus, it is a more hydrophobic material [248]. In addition, the water  
766 adsorption capacity can be obtained by the standard contact porometry and sorptometry which  
767 employ the mass change measures of the sorbents under constant water vapor pressure/humidity  
768 [249].

769

770 1.2.3.5 Calorimetric techniques

771 Calorimetry has been used to study solid surface of solids in liquid medium. Here, we will  
772 review one the most used calorimetric techniques to characterize solid surface affinity for water. This  
773 technique involves the measurement of the heat of immersion, also called heat of wetting or  
774 immersion enthalpy, which is the energy change at constant pressure and temperature when a solid  
775 is immersed in a liquid. The heat of immersion depends on both the chemical interactions of the liquid  
776 with the solid surface and the textural properties of the solid [32,228,250]. Therefore, characterization  
777 of microporous solids by calorimetry is not so simple due to the contributions of interactions of  
778 different nature [251]. This technique has been widely used to study the microporous material such  
779 as activated carbon and zeolites [252]. Silvestre-Alveró and co-authors used calorimetry of immersion  
780 to compare the hydrophobic character between Ti-MCM-41 and silylated Ti-MCM-41. They used  
781 different liquids as probe molecules, ranging from non-polar (i.e., hydrocarbons) and polar molecules  
782 (i.e., water, alcohols). According to their results, silylated Ti-MCM-41 demonstrated a hydrophobic  
783 character since the heat of immersion in water decreased for increasing silylation degrees. On the  
784 other hand, silylation displayed a lower effect on the heat of immersion measured in cyclohexane,  
785 indicating that the interactions between a hydrophobic surface with a non-polar liquid are smaller  
786 and probably also affected by the textural properties [250].

787

788 1.2.3.6 Solid State Nuclear Magnetic Resonance (Solid-State NMR)

789 The Nuclear Magnetic Resonance (NMR) spectroscopy consists in the application of a magnetic  
790 field strength. If a sample is placed in a magnetic field and it is radiated at the appropriate frequency,  
791 the nucleus of the sample can absorb energy. The radiation frequency necessary to generate  
792 absorption energy depends of the type of nucleus, the spatial location in the magnetic field, and the  
793 chemical environment [253,254].

794 Solid-state NMR can be used to evaluate the hydrophobic character of solids since the presence  
795 of hydrophilic sites (-OH) and organic moieties bonded to Si atoms can be determined. For example,  
796 the intensity of hydroxyl groups and molecular water signals can be measured from analyzing the  
797 <sup>1</sup>H NMR spectra at low temperature [228]. Additionally, some previous studies have used solid-state  
798 NMR to describe the degree of condensation of silicates by deconvoluting the <sup>29</sup>Si NMR spectrum  
799 using the contributions of Q<sup>4</sup> ((Si(OSi)<sub>4</sub>), Q<sup>3</sup> ((Si(OSi)<sub>3</sub>OH)), and Q<sup>2</sup> ((Si(OSi)<sub>2</sub>(OH)<sub>2</sub>)) (See Figure 8)  
800 [39,47]. Besides the condensation degree, this analysis is strongly related to the  
801 hydrophobicity/hilicity of the material since silanols (Si-OH) are hydrophilic sites, so the highest  
802 the fraction of Q<sup>3</sup> and Q<sup>2</sup> relative to Q<sup>4</sup> would indicate a hydrophilic character. If the hydrophobicity  
803 origin is the functionalization of the surface with organic fractions, solid-state NMR can be also used.  
804 For example, Muller et al, determined the fraction of Si bonded to methyl groups, in order to evaluate  
805 the effective methyl-functionalization of amorphous titanosilicates (Ti-SiO<sub>2</sub>) [47]. There are two  
806 modes for the experimental approaches of solid-state NMR. The cross-polarization mode allows to  
807 excite the contributions of T<sup>2</sup> and T<sup>3</sup>, so they are better appreciated even at low organic content.  
808 Nevertheless, this method cannot be used for quantification of each resonance. The direct excitation  
809 mode is applied for quantification, and once the spectra is recorded, contributions are quantified by

810 deconvolution of peaks using gaussian functions. Indeed, some previous studies have used cross-  
811 polarization to verify the surface functionalization [47].

812 Solid-state NMR cannot be used to study the Ti nucleus at very low Ti molar ratios [23]. Another  
813 nucleus that can be followed by solid-state NMR is  $^{13}\text{C}$ . In this case, the analysis provides information  
814 about organic functionalization or the degree of removal of the templating agents [255].

815

816 **Figure 8** Typical types of resonance contributions of a solid-state  $^{29}\text{Si}$  NMR spectra. Adapted from  
817 [47].

818 A summary of the analytic techniques employed for evaluation of hydrophobicity of  
819 titanosilicates is presented in table 4.

820 **Table 4** Analytic techniques for the characterization of hydrophobicity.

## 821 Section 2: Discussion of recent advances of the topic

### 822 2.1 Discernment of the results of the effect of the hydrophobic modification on the catalytic activity of 823 titanosilicates

824 Hydrophobization of titanosilicates has been proposed as a tool to improve their catalytic  
825 performance, hence several researchers embarked on this study to gain better understanding of this  
826 modification [2]. Some of them have found a positive effect of hydrophobization, but others have  
827 found a negative or negligible effect. This diversity in the points of view can be justified because there  
828 is a considerable number of variables influencing the catalytic performance of titanosilicates in  
829 oxidation reactions. The physical/chemical properties of each type of titanosilicate and the  
830 methodologies for hydrophobization affect their interactions with the reactants, products,  
831 intermediate species, and solvent. Furthermore, evaluating and comparing the hydrophobic

832 character of these materials are still a challenge due to the variety of analytical techniques applied to  
833 measure this property.

834 The catalytic effect of hydrophobizing titanosilicates could be studied for different model  
835 reactions (e.g., hydroxylation of phenol), each of them with different characteristics. The specific  
836 characteristics of each reaction make difficult the analysis of all these reactions as a single group;  
837 therefore, a comparison between effects of hydrophobization involved in all kinds of these reactions  
838 is outside the scope of this research. Nevertheless, in this work, the effects of hydrophobization over  
839 the catalytic activity in epoxidation reactions will be compared and discussed. The type of  
840 titanosilicate, the hydrophobization strategy, the surface characterization, and the catalytic system  
841 (reactants and solvent) will be considered. We have chosen the epoxidation of olefins since this  
842 reaction is represented in both fine and bulk chemical industry, and the epoxide is an important  
843 synthetic intermediate of organic transformations reactions [33,168,257]. Epoxides are used for the  
844 fabrication of epoxy resins, drugs, plasticizers, sweeteners and perfumery materials, among others  
845 [257]. Additionally, the epoxidation of olefins would be a good model to study the catalytic effects of  
846 adjusting the hydrophobic/hydrophilic character of catalyst surface since the olefin is hydrophobic  
847 while epoxide is hydrophilic, and thus, their interactions with catalysts are different. The epoxidation  
848 mechanism of olefins has been extensively studied, and it was found that epoxides can be produced  
849 by two competitive routes: the direct epoxidation, and the allylic oxidation (Figure 9). When the  $H_2O_2$   
850 is used as the oxidant, the direct epoxidation is mediated by the titanium-hydroperoxo complex (Ti-  
851 OOH). However, the presence of water in this reaction mixture promotes undesired epoxide ring  
852 opening which produces the corresponding diol. Diol can be also generated by the presence of acid  
853 sites on the catalysts surface. The allylic route is mediated by radicals (Ti-O· and HO·) which are  
854 formed by the homolysis of Ti-OOH. This route generates oxygenated products including epoxides,  
855 alcohols and ketones through consecutive reactions [258]. The mechanism of the direct epoxidation,  
856 which is our route of interest, has been studied and widely accepted to follow an Eley-Rideal  
857 mechanism. In this mechanism the oxidant (hydrogen peroxide or organic peroxide) adsorbs on the  
858 titanium active sites forming active intermediate species (Ti-OOR, where R=H or alkyl). These species  
859 react with the olefin producing the epoxide that is later desorbed from the surface of catalyst.

860

861 **Figure 9** Direct epoxidation and allylic route for cyclohexene oxidation. Adapted from [48,204].

862 In order to review the effect on the catalytic performance of hydrophobized titanosilicates, we  
863 will follow the order of the methodologies for hydrophobization since we believe the surface  
864 properties achieved by each methodology influence the catalytic activity. First, the control of the OH  
865 surface density will be analyzed, and later a discussion about the catalytic performance of  
866 functionalized titanosilicates will be addressed.

867 Modification of crystallinity in titanosilicates was used to regulate the amount of hydroxyl  
868 groups on the surface of TS-1. A YNU (Yokohama National University) method that consists in the  
869 use of  $(\text{NH}_4)_2\text{CO}_3$  as crystallization-mediating agent was applied to increase the crystallinity of TS-1.  
870 The characterization of the catalyst by DRUV-Vis spectroscopy presented a band attributed to FW-Ti  
871 at 210 nm, and no band above 250 nm appeared which showed that most of Ti atoms were introduced  
872 into the framework (nominal Si/Ti=34.2). This was also confirmed by the band at  $960\text{ cm}^{-1}$  of the IR  
873 spectrum attributed to Ti-O-Si. The formation of FW-Ti (tetrahedral coordination) within TS-1  
874 resulted in an increase of crystallinity and hydrophobicity due to the insertion of more Ti atoms  
875 which prevented the formation of defect sites (Si-OH). This was confirmed by IR and  $^1\text{H}$  and  $^{29}\text{Si}$  MAS  
876 NMR spectroscopies. The IR band at  $3738\text{ cm}^{-1}$  (corresponding to isolated Si-OH) and the Q<sup>4</sup>/Q<sup>3</sup> ratio  
877 decreased with the incorporation of FW-Ti. A lower amount of defect sites makes the surface  
878 hydrophobic preventing the attack by adsorbed water molecules and, consequently, a collapse of the  
879 zeolite framework. An enhanced activity (TONs and conversion) of TS-1 in the epoxidation of 1-  
880 hexene and styrene using  $\text{H}_2\text{O}_2$  as oxidant was attributed to a hydrophobic character [34].

881 Ti-Beta is one of the titanosilicates that has been hydrophobized by different methodologies  
882 [6,37,38], and one of them is the regulation of silanol surface density. It is known that the presence of  
883  $\text{Al}^{3+}$  heteroatoms introduces defects (Si-OH or Si-OH-Al) into the zeolite framework (when  
884 synthesized in OH<sup>-</sup> medium), conferring a hydrophilic character to Ti-Beta, but also more acidity (See  
885 section 1.2.2.1) [65]. Therefore, it was proposed that the synthesis of Ti-Beta by crystallization assisted  
886 by using dealuminated Beta seeds would produce more active Al-free Ti-Beta catalysts. These  
887 materials exhibited enhanced selectivity in the epoxidation of 1-hexene using  $\text{H}_2\text{O}_2$  as oxidant. As  
888 expected, the selectivity to epoxide (~40% at 60% conversion of 1-hexene) increased when the Al  
889 content decreased. However, even with Al-free Ti-Beta (Si/Al>5000), epoxide ring opening was still  
890 detected. The authors attributed this ring opening to the silanols or the Ti species of different acidity.  
891 In fact, this phenomenon was confirmed by comparing the catalytic oxidation of the epoxide in Al-  
892 free Ti-Beta (ring opening observed) with the oxidation in Al-free Beta zeolite (without Ti), in which  
893 no ring opening was observed [104]. From this work, it was possible to conclude that the removal of  
894 Al improves the selectivity for epoxide, probably due to the removal of strong acid sites, but the  
895 relation with hydrophobicity cannot be discarded. Besides the control of the Al content, other  
896 alternatives to produce more hydrophobic titanosilicates, encompass for instance the synthesis in  
897 fluoride medium.

898 In this context, dealuminated Ti-Beta was further hydrophobized as mentioned in the reports  
899 published by Blasco *et al.*, in 1996 [37] and 1998 [38]. In these works, the silanol density was controlled  
900 by using fluoride ( $\text{F}^-$ ) medium instead of aqueous ( $\text{OH}^-$ ) medium during sol-gel synthesis. Al-free Ti-  
901 Beta produced in  $\text{F}^-$  medium displayed improved crystallinity and very high thermal and  
902 hydrothermal stability. These improved characteristic in the Ti-Beta were verified according to the  
903 calcination process carried out at 1223 K where Ti-Beta ( $\text{F}^-$ ) kept its crystallinity and no significant  
904 losses of Ti were observed. In contrast, crystalline structure of Ti-Beta ( $\text{OH}^-$ ) was destroyed under the  
905 same conditions. In addition, Ti-Beta ( $\text{F}^-$ ) remained stable under a hydrothermal treatment (exposure  
906 to 100% humidity, at 1023 K). The hydrophobization of Al free Ti-Beta showed a positive effect in the  
907 catalytic performance when it was used in the epoxidation of methyl oleate [37] and 1-hexene [38].  
908 Ti-Beta ( $\text{F}^-$ ) was more active and selective to the epoxide than Ti-Beta ( $\text{OH}^-$ ), and the  $\text{H}_2\text{O}_2$  efficiency  
909 increased too. The higher selectivity was the result of the improved desorption of the epoxide from  
910 the hydrophobic Ti-Beta ( $\text{F}^-$ ) surface. The improved desorption of the epoxide prevents the epoxide  
911 ring to open which could occur if the epoxide remains long enough close to the active site [37,38]. The  
912 hydrophobic character of Ti-Beta ( $\text{F}^-$ ) was confirmed by X-ray absorption where the Ti K edge spectra  
913 (XANES) showed a prepeak with similar intensities in the calcined and in the rehydrated samples  
914 while the prepeak for Ti-Beta ( $\text{OH}^-$ ) significantly decreased its intensity and broadened upon  
915 rehydration. These results helped to conclude that there is a higher amount of Ti atoms that  
916 coordinate with adsorbed water molecules upon rehydration in the case of Ti-Beta ( $\text{OH}^-$ ) compared  
917 to Ti-Beta( $\text{F}^-$ ) [37].

918 Another study compared the catalytic activity and selectivity of Ti-Beta(F<sup>-</sup>) and Ti-Beta (OH<sup>-</sup>) for  
919 the epoxidation of 1-hexene and oleic acid using H<sub>2</sub>O<sub>2</sub> as oxidant and acetonitrile and methanol as  
920 solvents [38]. Characterization of the catalysts synthesized in (F<sup>-</sup>) medium showed that only 50% of  
921 Ti was incorporated in the final material due to the formation of soluble complexes of Ti with F<sup>-</sup> at  
922 low pH that precluded the total incorporation of Ti atoms into the zeolite. The addition of F<sup>-</sup> decreased  
923 the pH. At high pH values (OH<sup>-</sup> medium), 100% of Ti was incorporated in the Ti-Beta (OH<sup>-</sup>). FTIR,  
924 <sup>1</sup>H and <sup>29</sup>Si MAS NMR, and water adsorption techniques verified the hydrophobic character of Ti-  
925 Beta (F<sup>-</sup>). The number of Si-OH connectivity defects was lower in Ti-Beta (F<sup>-</sup>) than Ti-Beta (OH<sup>-</sup>)  
926 (contribution at 960 cm<sup>-1</sup> was higher for Ti-Beta (OH<sup>-</sup>)). <sup>29</sup>Si Bloch-decay (BD) MAS NMR indicated  
927 that the Q<sup>3</sup> contribution was not detected for Ti-Beta (F<sup>-</sup>), whereas <sup>1</sup>H and <sup>29</sup>Si cross-polarization (CP)  
928 MAS NMR spectroscopy reflected the presence of negligible concentrations of Si-OH groups at the  
929 external surface of Ti-Beta (F<sup>-</sup>). Contrarily, the concentration of Si-OH detected for Ti-Beta (OH<sup>-</sup>) was  
930 higher. Water adsorption experiments suggested that the Ti site of Ti-Beta (F<sup>-</sup>) adsorbed one molecule  
931 of water while Ti in the Ti-Beta (OH<sup>-</sup>) could adsorb more than one water molecule. The catalytic  
932 activity of Ti-Beta (F<sup>-</sup>) displayed no significant effect compared to that of Ti-Beta (OH<sup>-</sup>) reaching  
933 similar values of conversion of 1-hexene of around 41% in the case of acetonitrile and 26% in the case  
934 of methanol. But the selectivity to epoxide in acetonitrile was higher (100%) for both Ti-Beta (F<sup>-</sup> and  
935 OH<sup>-</sup>), while using methanol Ti-Beta (F<sup>-</sup>) exhibited higher selectivity to epoxide than Ti-Beta (OH<sup>-</sup>)  
936 (76.6% vs 54.9%). The low selectivity to epoxide using methanol (for Ti-Beta (OH<sup>-</sup>)) was attributed to  
937 the opening of the oxirane ring which occurred even in the complete absence of Al, as mentioned in  
938 the ref [104], intermediate species related with Ti could contribute to the epoxide ring opening.  
939 Finally, the difference in the hydrophobicity of the catalysts surface was more evident for oxidation  
940 of alkenes with a polar fraction, as seen in the case of methyl oleate [37] and oleic acid [38] where the  
941 catalytic performance of Ti-Beta (F<sup>-</sup>) was higher than Ti-Beta (OH<sup>-</sup>) [38].

942 Fluoride medium not only helped to obtain a more hydrophobic material through the control of  
943 silanol density but also prevented the deactivation of the active sites. Even though the content of  
944 tetrahedral Ti in the material synthesized in F<sup>-</sup> medium is lower compared with materials synthesized  
945 in OH<sup>-</sup> medium, the catalytic activity was comparable in both cases. However, the addition of F<sup>-</sup> ions  
946 into the synthesis must be carefully controlled since an excessive amount of them could affect the  
947 insertion of Ti in the framework. An excessive addition of F<sup>-</sup> ions leads to the formation of Ti(OH)<sub>x</sub>F<sub>y</sub>  
948 complexes, causing a unfavorable effect on the catalytic performance of titanosilicates (See section  
949 1.2.2.1) [192].

950 According to previous reports, hydrophobic catalysts performed better than hydrophilic ones.  
951 For instance, the hydrophobic TS-1 exhibited superior catalytic properties for the epoxidation of  
952 olefins compared to other hydrophilic titanosilicates such as Ti-Beta [90]. Therefore, several  
953 researchers focused on the improvement of the hydrophobicity of titanosilicates. Nevertheless, recent  
954 studies showed that the increase of silanol density enhanced the epoxide yields of cyclohexene and  
955 1-hexene [39,77,259–261]. Bregante et al. performed an extensive study about the catalytic  
956 epoxidation of alkenes with H<sub>2</sub>O<sub>2</sub> as oxidant and Ti-Beta as catalyst. It was concluded that water  
957 clusters anchored to silanol nests (SiOH)<sub>4</sub> (which correspond to hydrogen-bonded Si-OH) on the  
958 catalyst surface play an important role stabilizing the epoxidation species and thus achieving high  
959 epoxidation rates. This conclusion was drawn by comparing the catalytic activity of Ti-Beta catalysts  
960 with different contents of silanol nests. In the first step of the synthesis, commercial Beta zeolites with  
961 initial Si/Al ratios ranging from 12.5 to 250 were dealuminated creating vacancy defects which in a  
962 second step were partially occupied by Ti atoms producing materials with different remaining  
963 contents of silanol nests (SiOH)<sub>4</sub> and thus, with different degrees of hydrophilicity. Additionally, a  
964 hydrophobic Ti-Beta was synthesized in fluoride medium to produce silanol-free surface. These  
965 catalysts were used in the epoxidation of 1-octene with H<sub>2</sub>O<sub>2</sub>. Thermodynamic and kinetic analysis  
966 evidenced that turnover rates for epoxidation of 1-octene increased with higher (SiOH)<sub>4</sub> surface  
967 density, concluding that the most hydrophilic catalyst was the most active one. In fact, materials  
968 containing ~5 (SiOH)<sub>4</sub> per unit cell displayed rates that were 100 times greater than defect-free Ti-

969 Beta. Spectroscopic, thermodynamic, and kinetic studies indicated that these differences in the  
970 epoxidation activity were not related either with the nature of Ti active intermediate species (Ti-  
971 OOH) or the epoxidation mechanism, but with the molecular interactions between Ti-OOH, (SiOH)<sub>4</sub>  
972 density and polar surface [39].

973 Another approach to modify the hydrophobicity of titanosilicates is the direct functionalization  
974 or one-pot synthesis. For instance, the hydrophobicity of Ti-MCM-41 was modified by adding some  
975 organo-alkoxysilanes precursors, such as methyl [40,195,203], phenyl [40], vinyl [40] and pentyl [40]  
976 organo-alkoxysilanes. These modified catalysts were used on the oxidation of cyclohexene using  
977 TBHP and H<sub>2</sub>O<sub>2</sub> as oxidants. A significant improvement on the activity was observed with the  
978 methyl-functionalized Ti-MCM-41 [40,195,203]. The insertion of organic groups increased the  
979 hydrophobicity of the catalysts. TGA analysis of pristine and functionalized Ti-MCM-41, pretreated  
980 with saturated NH<sub>4</sub>Cl solution to reach the maximum water adsorption, confirmed the superior  
981 hydrophobicity of functionalized Ti-MCM-41 compared to the pristine analogous. Indeed, the  
982 number of water molecules adsorbed per nm<sup>2</sup> decreased as the incorporation of methyl groups on the  
983 surface increased. The silanol surface density was also evaluated by <sup>29</sup>Si MAS NMR spectroscopy by  
984 following the contributions of Q<sup>4</sup> (Si(OSi)<sub>4</sub>), Q<sup>3</sup> (HOSi(OSi)<sub>3</sub>), Q<sup>2</sup> ((HO)<sub>2</sub>Si(OSi)<sub>2</sub>), T<sup>3</sup> (RSi(OSi)<sub>3</sub>), and T<sup>2</sup>  
985 (R(HO)Si(OSi)<sub>2</sub>). Peak deconvolution allowed to quantify both the organic group bound to Si and the  
986 SiOH content expressed in mol%. It was possible to observe that the hydrolysis and condensation of  
987 organic precursors were affected by inductive, resonance and steric effects. For example, in the case  
988 of the methyl group, a low functionalization degree (Si-CH<sub>3</sub>/Si=8.9% and Si-OH/Si=65.8%) was  
989 reached, contrarily to the phenyl group which displayed a fast hydrolysis and a higher  
990 functionalization degree (Si-phenyl/Si=27.8% and Si-OH/Si=60.6%). Water adsorption measurements  
991 revealed that all functionalized Ti-MCM-41 adsorbed less water than the pristine material [40]. The  
992 DRUV-Vis characterization showed that octahedral Ti was present in the pristine samples, while  
993 tetrahedral Ti was principally detected in the methyl-functionalized samples [195].

994 Amorphous titanosilicates Ti-SiO<sub>2</sub> were modified by one-pot functionalization with  
995 phenyltrimethoxysilane (PHTMS) (nominal 30%). The BET surface areas of functionalized catalysts  
996 exhibited a reduction in the pore volume and average pore diameter compared with unmodified  
997 catalysts. The Ti dispersion was also affected by the insertion of phenyl groups. The organic  
998 functionalization was confirmed by the presence of T<sup>2</sup> and T<sup>3</sup> contributions in the <sup>29</sup>Si MAS NMR  
999 spectrum. The epoxidation of cyclohexene using both modified and unmodified Ti-SiO<sub>2</sub> was  
1000 compared using three different solvents, toluene, acetone, and ethanol. The initial epoxide  
1001 production rate and the epoxide yield (after 2 hours) were higher with all solvents using  
1002 functionalized materials compared with the pristine samples. These values increased in polar  
1003 solvents (acetone and ethanol) in comparison with toluene for the functionalized Ti-SiO<sub>2</sub>. The  
1004 selectivity to epoxide using functionalized materials was 95, 87 and 94% for toluene, acetone, and  
1005 ethanol, respectively. This was attributed to the presence of non-polar organic groups on the  
1006 modified surface catalyst which increased the hydrophobic character and improved the selectivity to  
1007 epoxide. A positive effect of one-pot insertion of organic groups on the catalytic activity could be  
1008 reached by properly choosing of the sol-gel parameters and the concentration of organic groups on  
1009 the catalyst surface since the steric effects and polarity modification (polar Si-OH replaced by organic  
1010 groups) affect the textural and chemical properties [46].

1011 As seen, one-pot functionalization with organic groups increased the hydrophobic character of  
1012 Ti-SiO<sub>2</sub> aerogels, but an excessive functionalization is detrimental for the catalytic performance. For  
1013 example, Ti-SiO<sub>2</sub> was modified by one-pot functionalization with methyl groups using  
1014 methyltrimethoxysilane, and effects on the Ti dispersion were evidenced. The formation of Ti in  
1015 tetrahedral coordination diminished due the direct functionalization method. According to the FTIR  
1016 spectrum, the pristine Ti-SiO<sub>2</sub> had a Si-O-Ti/Si-O-Si ratio of 0.75, whereas this ratio in methylated  
1017 materials was in the range of 0.49-0.57. It was suggested that Ti dispersion into the silica matrix was  
1018 reduced by the insertion of methyl groups. The deconvolution of <sup>29</sup>Si MAS NMR peaks showed that  
1019 the effective functionalization degree (Si-CH<sub>3</sub>/Si) was 25.6% (30% nominal). A negative effect was

1020 observed in the epoxidation of 1-hexene and cyclohexene using the methylated Ti-SiO<sub>2</sub>. This behavior  
1021 was attributed to three main causes: the lower surface area, the lower Ti dispersion and the pore  
1022 blockage due to excessive functionalization [47].

1023 The catalytic activity improves as the insertion of organic groups increases until a limit is  
1024 reached, after which, the catalytic performance is negatively affected. Indeed, one-pot methyl-  
1025 functionalization was attempted to produce hydrophobic Ti-SiO<sub>2</sub> with 1, 5 and 14% degrees of  
1026 methyl-functionalization. These catalysts were tested in cyclooctene epoxidation and H<sub>2</sub>O<sub>2</sub> as  
1027 oxidant. The trend of the initial epoxidation rate normalized by the fraction of Ti active sites showed  
1028 that the methyl-functionalized Ti-SiO<sub>2</sub> reached higher epoxidation rates. This behavior was attributed  
1029 to the improved affinity of the hydrophobic catalyst surface with the olefin and lower affinity with  
1030 the epoxide. However, at the maximum degree of methyl-functionalization of 14% (determined from  
1031 <sup>29</sup>Si DE MAS NMR measurements by the formula  $\%Me = (T^i / (\sum T^i - Q^i)) * 100$ ), the epoxidation rate  
1032 decreased even compared to the epoxidation rate of the reference (non-functionalized) Ti-SiO<sub>2</sub>. This  
1033 led the authors to suggest that an excessive functionalization could affect the adsorption of the  
1034 oxidant [45].

1035 An interesting comparison between one-pot and post-grafting functionalization of Ti-SiO<sub>2</sub>  
1036 synthesized by non-hydrolytic sol-gel (NHSG) method was published by Smeets and co-workers [48].

1037 The catalytic activity and water resistance were evaluated for the methylated Ti-SiO<sub>2</sub> (NHSG\_Ti-  
1038 SiO<sub>2</sub>\_Me) in cyclohexene epoxidation with H<sub>2</sub>O<sub>2</sub> as oxidant. To evaluate the catalytic activity of  
1039 NHSG\_Ti-SiO<sub>2</sub>\_Me, acetonitrile was used as solvent while an acetonitrile/water mixture (75:25 v/v)  
1040 was used to determine the water resistance. Prior to the use of methylated catalysts, pristine  
1041 NHSG\_Ti-SiO<sub>2</sub> was compared to TS-1, and both catalysts displayed a comparable catalytic activity in  
1042 acetonitrile, but NHSG\_Ti-SiO<sub>2</sub> displayed a lower epoxide yield (2.1% in comparison with 18.3%  
1043 obtained with acetonitrile) than TS-1 in acetonitrile/water mixture. However, the diol formation  
1044 increased for both TS-1 and NHSG\_Ti-SiO<sub>2</sub> due to oxirane ring opening caused by water. Hence, the  
1045 NHSG\_Ti-SiO<sub>2</sub> was functionalized by the one-pot method (NHSG\_Ti-SiO<sub>2</sub>\_Me) to prevent the oxirane  
1046 ring opening in the presence of water. However, this strategy negatively affected the activity even  
1047 more than pristine samples in acetonitrile/water mixture, this was attributed to capping of Ti active  
1048 sites by methyl groups. On the other hand, post-grafting was also applied to obtain functionalized  
1049 Ti-SiO<sub>2</sub> (NHSG\_Ti-SiO<sub>2</sub>@Me), and it displayed the same conversion (~13%) that NHSG\_Ti-SiO<sub>2</sub>, but  
1050 an enhancement in the epoxide yield (5.1% vs. 2.1%) was reached. The authors concluded that the  
1051 presence of water affected the mechanism of epoxidation not only by favoring the oxirane ring  
1052 opening, but also by deactivating the Ti active species, preventing the direct epoxidation route.  
1053 Activated intermediate species of Ti (formed by the coordination between Ti active sites and H<sub>2</sub>O<sub>2</sub>),  
1054 that are responsible for oxidizing the olefin, can be deactivated by a second hydrolysis [262–264].  
1055 Consequently, these deactivated species cause poor activity and epoxide yield. The functionalization  
1056 by post-grafting prevented the deactivation of titanium active sites while the textural properties of  
1057 catalysts were affected and probably, the active one were capped by one-pot functionalization [48].

1058 To overcome the limitation of Ti dispersion via one-pot synthesis, Ti-SiO<sub>2</sub> catalysts were  
1059 synthesized by aerosol-assisted one-pot sol-gel. From DRUV-Vis, XPS and ICP characterization,  
1060 higher content of framework Ti was detected in the modified catalysts which confirmed a high Ti  
1061 dispersion. According to the <sup>29</sup>Si direct-excitation (DE) MAS NMR results, the presence of T<sup>3</sup>  
1062 (Si(OSi)<sub>3</sub>Me) and T<sup>2</sup> (Si(OSi)<sub>2</sub>(OH)Me) were observed, which are absent in pristine samples. FTIR-ATR  
1063 spectra confirmed the presence of Si-C band at 1279 cm<sup>-1</sup>. Mass losses at high temperature (around  
1064 803 K) also evidenced the presence of methyl groups in the functionalized catalysts. In addition, the  
1065 hydrophobic character of methylated Ti-SiO<sub>2</sub> was proved by the TGA, <sup>29</sup>Si DE MAS NMR and  
1066 adsorption studies. Mass losses of physisorbed water normalized by the specific area and the water  
1067 affinity were higher in the unfunctionalized samples and lower in the functionalized samples [11].  
1068 The catalyst characterization indicated that the functionalization by aerosol-assisted one-pot sol-gel  
1069 was successful and when the catalysts were probed in the epoxidation of cyclooctene with TBHP, an  
1070 improved catalytic performance was shown with functionalized Ti-SiO<sub>2</sub> [11].

1071 Another functionalization method is post-grafting used to modify the hydrophobicity of  
1072 titanosilicates. For example, the hydrophobic character of Ti-MCM-41 and Ti-MCM-48 titanosilicates  
1073 was controlled by grafting organosilanes to silanol groups on the materials surface. Ti-MCM-41 and  
1074 Ti-MCM-48 were modified by trimethylsilylation using trimethylchlorosilane (TMCS) as silylating  
1075 reagent. The deconvolution of the  $^{29}\text{Si}$  MAS NMR spectrum into three contributions  $\text{Q}^4$ ,  $\text{Q}^3$  and the  
1076 peak of trimethylsilylation TMS ( $(\text{CH}_3)_3\text{Si}(\text{OSi})$  at  $\delta$  14.3) showed that the amount of silanol groups  
1077 was 0.263 mol Si-OH/mol Si and 0.208 mol Si-OH/mol Si before and after the silylation, respectively.  
1078 The incomplete silylation was attributed to the size of trimethylsilyl group (*ca.* 0.6 nm). Despite the  
1079 partial silylation (21% of Si-OH were silylated), TGA showed that the functionalized Ti-MCM-41  
1080 adsorbed much less water (0.29 mass%) than non-silylated ones (55 mass%). Prior to TGA analysis  
1081 samples were exposed to moisture over saturated aqueous solution of  $\text{NH}_4\text{Cl}$ . The hydrophobic  
1082 character of Ti-MCM-41 and Ti-MCM-48 improved the conversion and TON in the epoxidation of  
1083 cyclohexene resulting in a *ca.* 20-fold increase compared to the catalytic activity of the non-silylated  
1084 samples. Trimethylsilylation improved the olefin (no polar) adsorption on methylated Ti-MCM-41  
1085 and the interaction of the olefin with the active sites. In addition, the  $\text{H}_2\text{O}_2$  efficiency improved by the  
1086 trimethylsilylation [42].

1087 Igarashi et al. in 2007 probed several organosilanes such as trimethylchlorosilane (TMCS),  
1088 hexamethyldisiloxane (HMDSO) and hexamethyldisilazane (HMDS) as silylating reagents (alone or  
1089 forming mixtures) in the post-grafting of Ti-MCM-41 and Ti-MCM-48. Samples were evacuated at  
1090 273 °C before silylation to prevent the decomposition of TMCS due to the reaction with water  
1091 molecules adsorbed on the solid surface. According to the  $^{29}\text{Si}$  MAS NMR spectra of samples before  
1092 and after the silylation, the highest trimethylsilylation degree (according to the TMS peak) was  
1093 attained with HMDS (25% for Ti-MCM-41 and 26% for Ti-MCM-48). Even though the initial amount  
1094 of silanol groups ( $\text{Q}^3$ ) of Ti-MCM-41 was higher (49%) than Ti-MCM-48 (36%). In contrast, the lowest  
1095 degree of silylation was obtained with TMCS despite the pre-evacuation. On the other hand, IR  
1096 spectra of silylated Ti-MCM-41 with HMDS showed that in addition to the band at  $3600\text{ cm}^{-1}$   
1097 (corresponding to hydrogen-bonded silanol groups), a new band appeared at  $3700\text{ cm}^{-1}$  which was  
1098 attributed to new isolated silanol groups because of the reaction between HMDS with hydrogen-  
1099 bonded Si-OH. This fact can explain the higher silylation degree obtained with HMDS in contrast  
1100 with the TMCS and HMDSO [41]. The catalytic performance of silylated materials was proved in the  
1101 epoxidation of cyclohexene and cyclododecene without solvent and using acetonitrile and methanol  
1102 as solvents. Silylated catalysts displayed higher conversions and TONs than non-silylated catalysts  
1103 in all cases. For both silylated and non-silylated catalysts, the selectivity to epoxide was lower in the  
1104 absence of solvents, while the epoxide was the major product using solvents. In contrast, in the  
1105 cyclododecene oxidation with  $\text{H}_2\text{O}_2$  and TBHP, cyclododecene epoxide was preferentially formed  
1106 with both silylated Ti-MCM-41 and silylated Ti-MCM-48 with the difference that higher conversion  
1107 and selectivity were reached with TBHP (70% aqueous solution) than with  $\text{H}_2\text{O}_2$ . The diol product  
1108 was obtained only over the non-functionalized ones, in absence of solvent. Two possible explanations  
1109 for epoxide production were proposed: i) acetonitrile acted as a Lewis base neutralizing the acidity  
1110 of catalysts which prevented the epoxide ring opening, and ii) the polarity of acetonitrile that allows  
1111 the desorption of epoxide from catalysts surface. The enhanced activity using TBHP could be ascribed  
1112 to the amphiphilic nature of the organic oxidant which presents both hydrophobic and hydrophilic  
1113 parts, allowing it to solvate both organic and aqueous phases. Finally, the  $\text{H}_2\text{O}_2$  efficiency was  
1114 improved with silylated Ti-MCM-41 and Ti-MCM-48, as seen in previous studies [41].

1115 Another variable besides the silylating agent is the silylation time. In this line, Ti-MCM-41 was  
1116 silylated with TMCS for 9 hours (Ti-MCM-41(S9)) and 5 hours (Ti-MCM-41(S5)). These samples were  
1117 compared with the pristine Ti-MCM-41 in the catalytic epoxidation of 1-octene using  $\text{H}_2\text{O}_2$  and TBHP  
1118 as oxidants. Higher activities were reached with trimethylsilylated Ti-MCM-41(S9) (9.7% for  $\text{H}_2\text{O}_2$   
1119 and 13.8% for TBHP) compared with pristine Ti-MCM-41 (5.3% for  $\text{H}_2\text{O}_2$  and 4.8% for TBHP). New  
1120 features appeared in the  $^{29}\text{Si}$  MAS NMR spectra of Ti-MCM-41(S9) and Ti-MCM-41 at 11 ppm and 5.1  
1121 ppm, which were assigned to  $(\text{CH}_3)_3\text{SiOSi}(\text{OSi})_3$  and  $(\text{CH}_3)_3\text{SiOTi}(\text{OSi})_3$  species, respectively. The peak

1122 at 5.1 ppm increased with the silylation time and depended on the Ti content. On the other hand, the  
1123  $Q^4/Q^3$  ratio of the pristine Ti-MCM-41 was 2.4, while the  $Q^4/Q^3$  ratio of Ti-MCM-41(S9) was 4.7. This  
1124 last value did not differ greatly from Ti-MCM-41(S5)) where  $Q^4/Q^3$  ratio was of 4.4. It appeared that  
1125 silylation occurred mostly between titanol [(OH)Ti(OSi)<sub>2</sub>OSi(OSi)<sub>3</sub>, Q<sup>3</sup>] and TMCS, explaining why  
1126 the  $Q^4/Q^3$  ratio did not vary. Consequently, the enhanced activity of trimethylsilylated Ti-MCM-41  
1127 was related to both an increment of hydrophobicity of the catalyst surface and the formation of  
1128 catalytically active Ti species ((CH<sub>3</sub>)<sub>3</sub>SiOTi(OSi)<sub>3</sub>) [256].

1129 Ti-SBA-15 was functionalized with three silyl amides of varying chain length, Me<sub>2</sub>NSiMe<sub>2</sub>(R) (R:  
1130 methyl, n-butyl, orn-octyl) producing the Me\_Ti-SBA-15, Bu\_Ti-SBA-15 and Oc\_Ti-SBA-15 samples.

1131 Functionalized catalysts were used in the epoxidation of cyclohexene using H<sub>2</sub>O<sub>2</sub> as oxidant and  
1132 acetonitrile as solvent. In all cases, functionalized Ti-SBA-15 showed higher catalytic performance for  
1133 the epoxidation of cyclohexene than the corresponding non-functionalized ones. The improved yield  
1134 and selectivity were related not only to the surface hydrophobicity, but also to the modification of  
1135 the Ti active site. First, the hydrophobic character of the functionalized Ti-SBA-15 was confirmed by  
1136 TGA analysis of saturated samples (with saturated H<sub>2</sub>O atmosphere for 24 hours). The mass losses of  
1137 physisorbed water measured at temperature below 150°C were 32% and ~3% for the non-  
1138 functionalized and functionalized catalysts, respectively. A functionalization degree from 63% to 74%  
1139 of the total available OH sites was reached, including Si-OH and Ti-OH. This was determined by  
1140 combustion and TGA analysis and corroborated by <sup>1</sup>H solid-state NMR. To study the influence of the  
1141 surface functionalization over the Ti sites, the authors synthesized SBA-15 with silylated Si-OH  
1142 groups, and later, Ti was grafted to the surface to obtain a hydrophobic surface with only uncapped  
1143 Ti-OH. The selectivity to epoxide with this catalyst was comparable with the pristine Ti-SBA-15 and  
1144 lower than functionalized Ti-SBA-15, suggesting that Ti-OH sites favor the allylic route. Furthermore,  
1145 the remaining TiOH sites were silylated to produce (R)<sub>3</sub>SiOTi(OSi)<sub>3</sub> species which were believed to  
1146 favor direct epoxidation. Indeed, the epoxide selectivity was higher than the catalyst with Ti-OH and  
1147 silylated Si-OH, proving that the presence of Ti-OH played an important role in the selectivity to  
1148 epoxide. Epoxide selectivity decreased in the following order: Bu\_Ti-SBA-15 66% (silylated Si-OH  
1149 and Ti-OH) > Bu\_Ti-SBA-15 45% (silylated Si-OH) > Ti-SBA-15 11.6% (non-silylated) [33]. These results  
1150 confirmed the hypothesis that the selectivity to epoxide improved due to the higher hydrophobicity,  
1151 but mainly due to the presence of (R)<sub>3</sub>SiOTi(OSi)<sub>3</sub> species.

1152 Amorphous Ti/SiO<sub>2</sub> titanosilicates (this notation corresponds to amorphous titanosilicates which  
1153 Ti atoms were inserted into the silica by post-grafting) were post-modified to improve their stability  
1154 in water during epoxidation reactions. Conventional Ti/SiO<sub>2</sub> catalysts were modified with  
1155 polymethylhydrosiloxane (PMHS, MW=390 g/mol) for 1 hour and 16 hours (PMHS-1 and PMHS-16).

1156 An additional Ti/SiO<sub>2</sub> sample was modified with TMS. Pristine and functionalized Ti/SiO<sub>2</sub> were  
1157 tested in the epoxidation of 1-octene using TBHP as oxidant. In batch catalytic tests, Ti/SiO<sub>2</sub> modified  
1158 with PMHS displayed a decrease in catalytic activity compared with the pristine Ti/SiO<sub>2</sub>. This was  
1159 attributed to the reduced specific surface area and pore plugging. Moreover, the rate of catalyst  
1160 deactivation was studied using a flow system. In this experiment, 132 μmol/L of water were added  
1161 in the feed to the flow reactor, and the measured initial rate of deactivation of TMS Ti/SiO<sub>2</sub> was -  
1162 0.32%/h, whereas for both PMHS-1 and PMHS-16, the deactivation rates were -0.03%/h and -0.09%/h,  
1163 correspondingly. TBHP conversions measured after 50 hours in the flow reactor were 5.3%, 7.6%,  
1164 8.2%, 9.7% for Ti/SiO<sub>2</sub>, TMS Ti/SiO<sub>2</sub>, PMHS-16, and PMHS-1, respectively. Moreover, values of  
1165 selectivity averaged during 50 hours in flow reactor for PMHS-1 (82%) and PMHS-16 (93%) were  
1166 higher than pristine Ti-SiO<sub>2</sub> (79%) but lower than for TMS Ti/SiO<sub>2</sub> (100%). On the other hand, the  
1167 TON (epoxide (mol)/ Ti (mol)) for the pristine sample was higher than for PMHS-1 and PMSH-16.  
1168 After hot-water Soxhlet extraction (to simulate catalyst deactivation processes), Ti/SiO<sub>2</sub> exhibited 62%  
1169 drop in TON and 45% drop in conversion, whereas PMHS-1 displayed no loss of TON and loss of 8%  
1170 in conversion. This loss was attributed to Ti aggregation, and this was confirmed by DRUV-Vis  
1171 analysis, which showed that a significant amount of tetrahedral Ti sites transformed into octahedral

1172 Ti sites. Hence, PMHS post-grafting increased the hydrolytic stability of Ti-SiO<sub>2</sub> as a result of its  
1173 hydrophobic character [49].

1174 A summary of hydrophobization methodologies applied to titanosilicates which were discussed  
1175 in this section, is presented in table 5.

1176 **Table 5** Hydrophobization methodologies applied to titanosilicates.

Material	Hydrophobization technique			
	Improvement of crystallization	Synthesis in fluoride (F <sup>-</sup> ) medium	One-pot synthesis	Post-grafting
TS-1	[34]			
Ti-Beta		[37,38]		
Ti-MCM-41			[40,195,203]	[41,42,256]
Ti-MCM-48				[41,42,256]
Ti-SBA-15				[33]
Ti-SiO <sub>2</sub>	[11,45–48]			[49]

### 1177 Section 3: Current needs in the research area

1178 *3.1 Discussion of current challenges in understanding the effect of the hydrophobization of titanosilicates on*  
1179 *their catalytic activity.*

1180 Various titanosilicates were hydrophobized in an attempt to enhance their catalytic performance  
1181 on the basis that the olefin adsorption and epoxide desorption would be improved by a hydrophobic  
1182 catalyst surface. With the advance in catalyst synthesis, characterization and hydrophobization  
1183 methodologies, the nature of the active sites was identified as an important role-player in the  
1184 selectivity to epoxide. Thus, the fabrication of titanosilicates with high hydrophobicity and well  
1185 distribution of Ti active sites became crucial to promote the direct epoxidation over the allylic route.

1186 Several works have been published about this topic, but these results have not yet been compiled in  
1187 a review. In this context, we discuss about the challenges in understanding the effect of  
1188 hydrophobization of titanosilicates over the catalytic performance in the epoxidation of olefins  
1189 according to the hydrophobization methodology.

1190 The control of the surface silanol density was studied as an alternative to modify the  
1191 hydrophobicity of titanosilicates. For example, the use of (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> (crystallization-mediating agent)  
1192 improved the crystallization process of TS-1. This facilitated the insertion of Ti into the zeolite  
1193 framework and lowered the number of defect sites (Si-OH), increasing the hydrophobicity of TS-1.  
1194 The more hydrophobic TS-1 displayed a higher resistance to water attack and better catalytic activity.

1195 However, in this case, the positive catalytic effect cannot be totally attributed to hydrophobicity  
1196 considering that the crystallization process increased the incorporation of FW-Ti which could be the  
1197 main reason for the enhanced catalytic activity.

1198 TS-1 is known for its hydrophobicity and good catalytic performance in epoxidation of small  
1199 substrates. However, titanosilicates with better textural properties had to be synthesized for larger  
1200 substrates. This is the case of Ti-Beta that was originally an aluminosilicate. The aluminum content  
1201 increased the hydrophilicity and acidity of the Ti-Beta surface which is undesirable for the  
1202 epoxidation reaction. For this reason, two strategies were developed to reduce the hydrophilicity (Si-  
1203 OH, Si-OH-Al) and acidity of Ti-Beta: i) dealumination and post-insertion of titanium (Ti), and ii)  
1204 direct synthesis in fluoride (F<sup>-</sup>) medium. In the first strategy, the number of remaining vacancies  
1205 (silanol nests) caused by dealumination decreased with Ti incorporation, while in the second strategy,  
1206 the vacancies were totally eliminated by the action of fluoride (F<sup>-</sup>) anions, rendering a more  
1207 hydrophobic character to the catalyst. In general, the hydrophobic Ti-Beta were more selective to  
1208 epoxide due to the improved epoxide desorption and reduced water adsorption, preventing the  
1209 oxirane ring opening and deactivation of Ti sites. However, a lack of agreement about the effect of

hydrophobization over the catalytic activity arose from comparing the results of some studies. For example, some authors found that the catalytic activity of hydrophobic Ti-Beta synthesized in F<sup>-</sup> medium was comparable to the activity of hydrophilic Ti-Beta synthesized in OH<sup>-</sup> medium. In contrast, a recent study determined that Ti-Beta (F<sup>-</sup>) was the least active compared to hydrophilic Ti-Beta which contained silanol nests (hydrogen-bonded silanols). The contrast in the measured catalytic activities in both studies could be attributed to the different synthesis procedure. In the case of the hydrophilic Ti-Beta (OH), the synthesis produces a material that has isolated and hydrogen-bonded silanols on the surface, but in the case of hydrophilic Ti-Beta obtained from dealumination and post-insertion of Ti, the material contains vacancies that improved the catalytic activity in the presence of hydrogen-bonding reactants. This indicates that the synthesis procedure has an important effect over the surface chemistry of the material, which consequently impacts its catalytic activity.

One-pot functionalization has also been tested as a methodology to synthesize more hydrophobic Ti-MCM-41 and Ti-SiO<sub>2</sub> using precursors such as organo-alkoxysilanes and organo-chlorosilanes. In general, it has been observed that the modified catalysts exhibited improved catalytic activity and selectivity in comparison with the pristine samples. The authors attributed the positive effect of hydrophobization to the improved affinity for the olefin, easy epoxide desorption and less water adsorption. The latter avoids the oxirane ring opening, which improves the selectivity to epoxide. The authors also observed that the excessive functionalization was detrimental to the catalytic performance since the textural properties and the Ti dispersion were affected. In fact, the specific surface area, pore diameter, and pore volume decreased due to pore blockage. Moreover, the formation of tetrahedral Ti was affected due to the addition of the organic precursor during synthesis.

Thus, the success of one-pot functionalization for titanosilicates depends on factors such as steric effects (organic group size), polarity of the organic group, and organic precursor ratio that affect the hydrolysis and condensation reactions during the synthesis. To prepare materials with better catalytic properties, one-pot functionalization has been optimized by applying pre-hydrolysis of precursors and appropriate drying conditions. Recently, the aerosol-assisted sol-gel synthesis method helped to tackle the limitations of one-pot functionalization by producing hydrophobic Ti-SiO<sub>2</sub> with controlled textural properties and Ti dispersion.

Post-grafting with organosilanes, hexamethyldisiloxane (HMDSO), hexamethyldisilazane (HMDS), and silyl amides has been used to hydrophobize Ti-MCM-41, Ti-MCM-48, Ti-SBA-15 and Ti-SiO<sub>2</sub>. All functionalized titanosilicates displayed better olefin conversion, selectivity to epoxide, and oxidant efficiency than the pristine analogous. This enhanced catalytic performance was mainly explained by the improved interaction between the olefin and the Ti active site on a hydrophobic surface where silanols were replaced by organic groups. Additionally, the higher selectivities were attributed to reduced deactivation of Ti sites and oxirane ring opening caused by the presence of water in the medium of reaction. Some authors realized that post-grafting could be used to functionalize both silanols and titanols on the surface of Ti-MCM-41 and Ti-SBA-15. Indeed, Brutchey et al demonstrated that a preferential functionalization of titanols modifies the nature of the Ti sites. The functionalized Ti is more electron-deficient, which increases the electrophilicity of the oxygen closer to the Ti center in the active intermediate species, favoring the direct epoxidation route.

Functionalized titanosilicates either by one-pot method or post-grafting consistently displayed higher conversions and selectivities in the epoxidation of olefins as a result of their hydrophobicity.

However, isolating the effect of hydrophobization was not possible in many studies since the hydrophobization methodology had an impact over the Ti active sites and textural properties.

In most of the articles presented in this review, hydrophobization strategies improved the catalytic performance, but other factors such as the nature and number of the active sites, the titanosilicate surface chemistry, the type of oxidant, the polarity and basicity of the solvent, the polarity and size of the olefin, and the environment surrounding the active site could not be disregarded. In fact, the direct epoxidation route depends on the electrophilicity (strength of the Lewis acidity) of the Ti active species. Moreover, the choice of the oxidant also plays an important

1261 role, since the reaction route depends on the electrophilicity of the active intermediate species. It is  
1262 known that Ti-OOR (R=alkyl), formed from the activation of an organic hydroperoxide with the Ti  
1263 active sites, displays lower electrophilicity than Ti-OOH, formed from the activation of hydrogen  
1264 peroxide with the Ti active sites. The alkyl group is an electron-donor group that decreases the  
1265 electrophilicity of the oxygen-donating species for epoxidation [23].

1266 In addition, the hydrophobic character of the modified titanosilicates originates from different  
1267 chemical properties. In some cases, the hydrophobicity is related to the silanol surface density and  
1268 the type of silanol (isolated or hydrogen-bonded silanols), whereas in other cases, the hydrophobicity  
1269 is related to the functionalization degree with organic moieties. Therefore, there is not a specific  
1270 characterization technique to measure the hydrophobicity of a catalyst.

1271 As explained in section 1.2.3, measuring the hydrophobicity/philicity of a catalyst surface  
1272 remains a challenge considering all the analytical techniques available and their respective theoretical  
1273 basis. Therefore, a combination of these techniques is required to reach a more precise surface  
1274 characterization. In fact, the combination of two or more analytical techniques has been successful at  
1275 ranking titanosilicates according to their hydrophobic character in each research work. However,  
1276 comparison of the hydrophobicity among materials from different studies has not yet been achieved.

1277 We consider that the quantification of the hydrophobic character could improve if it is expressed as  
1278 the number of hydrophilic sites or degree of organic functionalization per specific surface area.

1279 Even if hydrophobicity is successfully measured, this property will not totally reflect the  
1280 behavior of the catalyst under the reaction conditions since epoxidation in liquid phase involves  
1281 different interactions between the catalyst surface and the liquid medium, which is composed of the  
1282 olefin, oxidant, solvent, and active intermediate species; all of them with different polarities.

1283 To conclude, a great development on the study of hydrophobicity and the effects on the catalytic  
1284 activity of titanosilicates has been reached from the contributions cited in this review; nevertheless,  
1285 more systematic studies that combine spectroscopic, thermodynamic, kinetic, and even  
1286 computational analysis are required to gain more understanding about the interactions between the  
1287 catalyst surface and the liquid-phase reaction medium.

1288 This review focused on the catalytic performance of hydrophobized titanosilicates in olefin  
1289 epoxidation, but this discussion could have implications for other reaction systems such as those for  
1290 biomass valorization, where the interaction between the hydrophobic/hydrophilic catalyst surface  
1291 with water is decisive.

1292 **Supporting Research Project:** This work is supported by the internal non-funded research project PII-DEMEX-  
1293 2020-03 developed in the Department of Extractive Metallurgy of Escuela Politécnica Nacional.

1294 **Acknowledgments:** A.B.L.M acknowledges all the support from Department of Extractive Metallurgy of Escuela  
1295 Politécnica Nacional and Santiago Molina.

### OTHER TYPES OF TITANOSILICATES

Several types of titanosilicates have been modified hydrophobically and these were described in the section 1.1.1. Other titanosilicates such as Ti-MWW and Ti-MOR with important applications are described in this part.

#### A1.1 Ti-MWW

Ti-MWW is a medium pore Ti-zeolite with 2-dimensional sinusoidal system of 10-MR, structural diversity of supercages (7.1 x 18.1 Å) and side pockets that enhance the catalytic activity because they act as reactions spaces where bulky substrates are accommodated (Figure A1) [1,2].

Figure A1 Topology of MWW zeolite framework [1].

The Ti(IV) substitution into the MWW zeolite framework was achieved by hydrothermal synthesis in boric acid media and using the SDAs, piperidine [3] or hexamethylene imine (HM) [4]. The MWW borosilicate crystalline structure (known as MCM-22) can be obtained from lamellar precursor by a dihydroxylation between layered sheets during the calcination process [5]. The titanosilicate Ti-MWW can be prepared by the same process and post-synthesis methods can be applied to form Ti-MWW with better accessibility to active sites, such as the preparation of

hierarchical Ti-MWW by the appropriate interlayer silylation with dimeric silane [6] and the reversible structural conversion of MWW for preparation of interlayer-expanded Ti-MWW [7]. Both materials were highly active in the epoxidation of cyclohexene using  $H_2O_2$  as oxidant. Ti-MWW has been used as a successful catalyst in ammoxidation of cyclohexanone [8], liquid-phase oxidation of cyclohexane [9], epoxidation of alkenes [10] and selective oxidation of pyridine [11].

## AI.2 Ti-MOR

Zeolites with MOR framework are a type of aluminosilicates synthesized by hydrothermally method without the use of SDAs. They are an important group of catalysts used in petrochemical processes [12,13]. Incorporation of titanium atoms into dealuminated MOR zeolite to prepare Ti-MOR was studied with the use of post-synthesis method using  $TiCl_4$  vapor, this method was called as “atom-planting” method [14]. A scheme of the preparation of Ti-MOR by dealumination and a solid-gas reaction between dealuminated MOR and  $TiCl_4$  is shown in Figure A2[15].

**Figure A2** Preparation of Ti-MOR by dealumination a solid-gas reaction between dealuminated MOR and  $TiCl_4$  [15].

Directly hydrothermal synthesis cannot be used due to the specific structure features that makes the crystallization of MOR framework impossible in silicious conditions and in absence of alkali source [15]. In the preparation of Ti-MOR, the molecules of  $\text{TiCl}_4$  should diffuse into the 12-MR channels to be effectively incorporated into the structure. This allows a better contact with the reactant molecules when Ti-MOR is used as catalyst in liquid-phase oxidation reactions [16]. Ti-MOR is a large pore Ti-zeolite with parallel 12-membered ring (MR) ( $6.5 \times 7.0 \text{ \AA}$ ) and 8-MR ( $2.6 \times 5.7 \text{ \AA}$ ) channels [16,17]. Ti-MOR has been demonstrated to be an efficient catalyst with higher activity than TS-1 in the hydroxylation of aromatics [18,19] and ammoximation of ketones [20] such as ammoximation of cyclohexanone in a continuous reactor [15,21] and ammoximation of dimethyl ketones [17].

### INTERMOLECULAR INTERACTIONS

For understanding the basics of hydrophobicity, it is convenient to review the intermolecular interactions.

#### All.1 Van der Waals interactions

The term "van der Waals forces" collectively encompasses the forces of attraction between molecules. They are weak attractive forces that are established between electrically neutral molecules (both polar and nonpolar), but they are very numerous and play a fundamental role in many chemical and biological processes [22].

##### All.1.1 Dipole-dipole interactions (Orientational or Keesom)

A molecule is dipolar when there is an asymmetric distribution of electrons because the molecule is formed by atoms with different electronegativities. As a consequence, the electrons are preferably in the vicinity of the most electronegative atom. Thus, two regions (or poles) are created in the molecule, one with a partial negative charge and the other with a partial positive charge. When two polar molecules (dipolar molecules) come together, there is an attraction between the positive pole of one of them and the negative pole of the other. This attractive force between two dipoles is more intense the greater the polarization of said polar molecules or, in other words, the greater the difference in electronegativity between the bonded atoms. The dipole moment ( $\mu$ ) is a vector oriented towards the negative charge whose magnitude depends on the intensity of the charge and the distance between the atoms. The dipole moment allows to quantify the asymmetry of charges in the molecule. The shape of the molecule also affects the dipole moment [23].

Dipole-dipole interactions are substantial only in systems with very polar molecules or in the case of small molecules with very large dipole moments such as ammonia (N-H), hydrogen fluoride (F-H) and water (O-H). These interactions are more complex and are called "hydrogen bonding" interactions [24]. The hydrogen bonds are shorth-range directional interactions, between very polar molecules, and the hydrogen atom is the center of positive charges that will be attracted to the unshared pairs of electrons from the electronegative atoms of other molecules. It is a weak

bond. However, as they are very abundant, their contribution to the cohesion between biomolecules is great [23].

### **All.1.2 Dipole-induced interactions (Induced or Debye)**

These interactions take place between a polar molecule and an apolar molecule. In this case, the charge of a polar molecule causes a distortion in the electron cloud of the apolar molecule and transiently converts it into a dipole (induced dipole). In this way, an attractive force is established between the molecules [24].

### **All.1.3 Instantaneous dipole-induced interactions (Dispersion or London)**

Dispersion forces are weak forces that are established mainly between nonpolar substances, although they are also present in polar substances. They occur due to the irregularities that exist in the electronic cloud of the atoms of the molecules as a result of mutual proximity. The presence of an instantaneous dipole in a molecule causes the formation of an induced dipole in a neighboring molecule so that a weak attractive force is created between the two molecules [22].

The side or end where the nucleus is partially exposed is slightly more positive ( $\delta^+$ ), and the end towards which the electron density has shifted has a partial negative charge ( $\delta^-$ ). This separation of charges is known as an instantaneous dipole. The partially exposed nucleus of an atom attracts electron density from a neighboring atom, and it is this induced dipole between molecules that represents the scattering force between atoms and molecules. However, an instant later the electron density has already shifted, and the partial charges causing the attraction have changed. The intensity of the dispersion force depends on a number of factors. However, taking a qualitative and predictive approach must consider that the dispersion forces are related to the number of electrons found in the atom or in the molecule. Thus, it is the number of electrons that will determine the ease with which the density of the electron can be polarized and a greater polarization, the dispersion forces are more intense [24,25].

Dispersion forces are long-range interactions (10 nm or more), they may be repulsive or attractive and they are nonadditive due to the presence of other near atoms and molecules affect the interactions between two specific atoms and molecules [24].
